Pharmacokinetic properties: TCAs are extensively metabolized and are CYP 450 enzyme substrates. In people, coadministration of drugs that inhibit the CYP 450 enzyme that is important for their metabolism can cause a fourfold increase in serum levels of TCAs. Drugs of the selective serotonin reuptake inhibitor class, described below, are potent inhibitors of CYP 450 enzymes (Mealey, 2002). Despite these potential risks, specific reports in the veterinary literature of drug interactions caused by coadministration of other drugs with TCAs are lacking. One reason for the lack of reported problems may be the high systemic clearance compared to humans, which indicates that there is less influence on changes in enzyme activity (discussed in more detail in Section Clomipramine) and the high therapeutic index in animals. Nevertheless, because of the potential for drug–drug interactions in humans, caution is advised when prescribing a TCA with other drugs known to affect drug metabolism. Because of the time to reach pharmacokinetic steady-state, and the time for modulation of the receptors affected by TCAs, therapeutic effects may not be seen for 2–4 weeks. Generally, withdrawal syndromes have not been a problem in animals. Nevertheless, to avoid the possibility of such reactions and to avoid a rebound of the problem being treated, slow discontinuation of any TCA is recommended.

The TCAs have also been used to treat pain syndromes. As reviewed by Micó et al. (2006), there is good evidence that TCAs are effective in people for treating pain, especially neuropathic pain, and may be used in combination with other drugs. Some veterinarians have also used these drugs for treatment of pain, although there are no published reports. The mechanism for analgesia is not entirely understood. It is probably not via the same mechanism that affects anxiety and depression because the analgesic effects have been documented to occur at lower doses and the onset of pain relief occurs faster than relief from depression and anxiety. The proposed mechanism of action for analgesia is via increased availability of norepinephrine and serotonin at the synapse, but other neurotransmitters also could be involved. Amitriptyline seems to be the gold standard for analgesic uses, and other antidepressants, such as SSRIs, do not appear to be as effective. Of note, the drug tramadol (Ultram) used for treatment of pain (discussed in Section Tramadol and in Chapter 13) has some opioid effects, but, in addition, has similar effects to TCAs – inhibition of serotonin and norepinephrine reuptake.

Adverse effects: Adverse effects may occur soon after administration of the drug or after chronic use. Side effects include mild sedation, gastrointestinal side effects – especially vomiting – antihistamine effects, and anticholinergic effects (Nelson, 2009). Anticholinergic effects may include dry mouth (and consequent increased water consumption), constipation, and urinary retention. The use of TCAs is contraindicated in cases of glaucoma or keratoconjunctivitis sicca. Tricyclic antidepressants may also lower seizure threshold and potentiate seizures in predisposed animals (Juarbe-Diaz, 1997a). Agranulocytosis has been associated with TCA administration, but it is rare (Alderman et al., 1993).

A particularly serious adverse effect is possible when TCAs are administered at high doses, as in an accidental ingestion by a pet, for example. High concentrations of TCAs can cause a quinidine-like membrane-stabilizing effect that can lead to fatal cardiac arrhythmias if patients are not treated promptly (Nelson, 2009; Johnson, 1990; Wismer, 2000). If animals receive a high dose (a toxic dose may be over 15 mg/kg), an ECG should be monitored immediately for conduction disturbances. If available, blood pressure should be monitored as well. Treatment of overdoses should be initiated at once, because deaths have occurred within 2 hours. Contact an animal poison control center for specific therapy. Treatment consists of gastric lavage, activated charcoal, a suitable cathartic (*not* containing magnesium), and sodium bicarbonate therapy. Antiarrhythmics that do not affect conduction may be indicated, such as lidocaine, but other class I antiarrhythmics such as procainamide and quinidine are contraindicated (antiarrhythmic drugs are discussed in more detail in Chapter 22).

The cardiotoxic effect described above should not be confused with the effect on the heart produced as an anticholinergic side effect or adrenergic blockade by TCAs. These drugs may elevate heart rate in some individuals caused by the anticholinergic effects, or lower the heart rate in others as a reflex response to the α_1-adrenergic effects. Before administering a TCA to animals, it is suggested to conduct a cardiac assessment (evaluate history, auscultate, ECG if indicated) prior to administration (Pacher et al., 1999). In a study in which effects on the cardiac ECG were evaluated in otherwise healthy dogs administered either clomipramine or amitriptyline, there was no evidence of ECG abnormalities (Reich et al., 2000). In this study, the drugs were administered at doses recommended for treatment of behavior problems.

TCAs may be difficult to administer directly or disguised in food since they have a lingering bitter taste. Biting the tablet can induce taste aversion, future dosing avoidance, and hypersalivation.

Amitriptyline

Amitriptyline is used in humans for depression, anxiety disorders, and for certain types of chronic or neuropathic pain (Anderson, 2001). It exerts active reuptake inhibition on serotonin receptors relative to norepinephrine receptors. It has strong anticholinergic, antihistamine, α_1-adrenergic, and analgesic properties (Anderson, 2001; Nelson, 2009). Nortriptyline, also commercially available (Pamelor), is the active metabolite (Anderson, 2001; Boothe, 2001).

Amitriptyline (Elavil) has been a useful drug in animals to enhance behavioral calming and augment a behavioral treatment program (Anderson, 2001; Hart and Cooper, 1996). In dogs, amitriptyline has been used for treatment of separation anxiety (Takeuchi et al., 2000), aggression (Anderson, 2001; Reich, 1999), and repetitive self-trauma (Overall, 2013, 1998b). The time for maximum effect is 2–4 weeks (Anderson, 2001). In cats, amitriptyline has been used for psychogenic alopecia (Sawyer et al., 1999).

Reported side effects in cats include weight gain, somnolence, and decreased grooming (Chew et al., 1998). Once-a-day, nighttime dosing is recommended to avoid excessive daytime sedation (Chew et al., 1998). Because there is a generic formulation, it has been popular among veterinarians desiring inexpensive treatments for patients.

Among the most common use in cats is administration for urinary disorders. It has been used for urine marking and inappropriate urination secondary to idiopathic interstitial cystitis (Chew et al., 1998). Amitriptyline stimulates β-adrenergic receptors in smooth muscle, including the urinary bladder, to cause a decrease in smooth muscle excitability and an increase in bladder capacity (Anderson, 2001; Chew et al., 1998). It also has been one of the more effective drugs for treating pain syndromes (Micó et al., 2006). For these reasons, it has been used to treat feline interstitial cystitis at an initial dose of 10 mg/cat once in the evening (Chew et al., 1998; Buffington et al., 1999). It is not known if an analgesic effect or behavior-modifying effect plays a role in the efficacy for treatment of this disease.

Imipramine

Imipramine (Tofranil) is a TCA with properties similar to amitriptyline except that imipramine has similar affinity for norepinephrine and serotonin receptors. Imipramine has only moderate affinity for histamine-H_1, or muscarinic (anticholinergic) receptors. Imipramine has more serotonergic activity, fewer anticholinergic effects, and modest α-agonist properties. In humans, imipramine has an elimination half-life of approximately 12 hours. Pharmacokinetics have not been reported for dogs, but empirically it has been administered twice daily to dogs.

Imipramine has been successfully used in humans to treat panic disorder in adults and nocturnal enuresis (bed-wetting) in children. It is a modestly priced treatment for narcolepsy in dogs and horses (Coleman, 1999). Imipramine may be used to treat separation anxiety (Marder, 1991; Overall et al., 2001), particularly in those cases in which urine house-soiling is problematic (Sherman, pers. obs.). Imipramine may also be used in cases of estrogen-dependent urinary incontinence in dogs intolerant to phenylpropanolamine. In one study of laboratory beagles, after 14 days treatment at a high dose (10 mg/kg q 24 h), imipramine improved abnormal "withdrawn and depressed" behavior (Iorio et al., 1983).

Clomipramine

Clomipramine (Clomicalm, veterinary label; Anafranil, human label) has the most serotonergic activity of all the TCAs. It is approved in humans for the treatment of obsessive–compulsive disorder (OCD) and was the first veterinary drug approved by the FDA to treat separation anxiety in dogs.

Dogs metabolize clomipramine more rapidly than humans, which affects clinical use. The average half-life in dogs is 5 hours (King et al., 2000a) to 7.2 hours (Hewson et al., 1998a) after single dose administration, and 2.1–4 hours after repeated doses (King et al., 2000b) The half-life of, desmethylclomipramine, an active metabolite, is 2.9 hours (King et al., 2000a), 1.9 hours (Hewson et al., 1998a), and 2.2–3.8 hours after multiple doses (King et al., 2000b). By comparison, the half-life in humans is 24 hours (Nelson, 2009) to 33 hours, and has been reported to be as high as 36–50 hours (Evans et al., 1980). The systemic clearance in dogs is rapid (23.3 ml/kg/min). The evidence indicates therefore, that in dogs, clomipramine is a high clearance drug for which hepatic blood flow is the most important factor in clearance. Changes in enzyme activity (cytochrome P450 alterations) or protein binding are not expected to affect clomipramine pharmacokinetics as it does in humans.

Oral absorption is only 16–20% in dogs (King et al., 2000a); the low systemic availability is probably reduced because of first-pass hepatic clearance. There are also differences between humans and dogs regarding metabolite profile. In dogs, the ratio of clomipramine to the desmethylclomipramine metabolite is 3 : 1, whereas in people this ratio is only 1 : 2.5. Clomipramine is believed to act primarily as a serotonin reuptake inhibitor, but the desmethyl metabolite is probably most responsible for the anticholinergic side effects. This may explain why there appears to be fewer anticholinergic side effects in dogs compared to people from this drug.

Despite the relatively short half-life in dogs, it has been effective when administered every 12 or 24 hours (King et al., 2000b). Clomipramine has been effective for treatment of canine compulsive disorder (Hewson et al., 1998b; Seksel and Lindeman, 2001) such as tail chasing (Moon-Fanelli and Dodman, 1998), or acral lick granuloma (Goldberger and Rapoport, 1991; Rapoport et al., 1992). Clomipramine (Clomicalm) is approved in the USA for the treatment of separation anxiety in dogs (King et al., 2000b; Simpson, 2000). Although there has been debate concerning the relative merits of behavioral versus pharmacological components to treatment (Podberscek et al., 1999), dogs treated with clomipramine (1–2 mg/kg q 12 h) for separation anxiety and video recorded when left alone showed reduction in anxiety-related behaviors compared to pretreatment control periods (Cannas et al., 2014). In one study, clomipramine was no more effective than controls for the treatment of dominance-related aggression in dogs (White et al., 1999). Clomipramine may be helpful in some cases of noise phobia (Seksel and Lindeman, 2001), but additional treatment with a benzodiazepine, such as alprazolam, may be necessary (Crowell-Davis et al., 2003). When clomipramine compared to placebo was given to dogs every 12 hours for 7 days prior to prior to transport, dogs reduced signs of fear and anxiety and reduced plasma cortisol levels (Frank et al., 2006).

Clomipramine has been used in cats to manage urine spraying (DeHasse, 1997; King et al., 2004), hyperesthesia (Sherman, pers. obs. 2000–2002), and some feline compulsive behavior, including psychogenic alopecia (Sawyer et al., 1999). A study of the pharmacokinetics of clomipramine and its active metabolite desmethylclomipramine after single-dose intravenous and oral administration showed marked pharmacokinetic variability and an average half-life of 12.3 h was calculated for intravenous clomipramine (Lainesse et al., 2006). Another study of single-dose oral clomipramine revealed significant sex-related differences in pharmacokinetics parameters (Lainesse et al., 2007). The results of these studies suggest potential genetic variability in clomipramine metabolism and an explanation for the variability in clinical response observed in cats.

Selective Serotonin Reuptake Inhibitors

As the name implies, selective serotonin reuptake inhibitors (SSRIs), are more specific than the TCAs. SSRIs block the reuptake of serotonin, making more available in the synapse, with little effect on the reuptake of norepinephrine (Figure 18.3).

The SSRIs include fluoxetine (Prozac, human label), paroxetine (Paxil), sertraline (Zoloft), fluvoxamine

(Luvox), citalopram (Celexa), and escitalopram (Lexapro). All are approved by the FDA for treatment of depression in humans. SSRIs are efficacious for the treatment of panic disorder in humans (Tollefson and Rosenbaum, 1998). Fluoxetine was approved by the FDA for treatment of dogs (Reconcile, veterinary brand), but the company withdrew the product from marketing. The FDA approval supported efficacy and safety in dogs (Simpson et al., 2007). Often a low dose is used to initiate therapy, and then it is titrated upward as necessary (Zahajzky et al., 2009). Most SSRIs have been shown to be effective in treatment of human obsessive–compulsive disorder (Tollefson and Rosenbaum, 1998).

In dogs, SSRIs have been used clinically for management of separation anxiety (Simpson et al., 2007), compulsive behaviors, and dominance-type (Dodman et al., 1996a) or impulsive aggression (Peremans et al., 2005). In cats, SSRIs are used to treat urine spraying, aggression, and compulsive behavior such as psychogenic alopecia and fabric chewing. Due to concerns about GIT adverse effects, cats medicated with SSRIs should be closely monitored for food and water consumption, and fecal and urinary elimination, as well as body weight. In horses, there is little known about the metabolism and effects of SSRIs.

There is evidence that individuals of several species who exhibit violent behavior have low CNS serotonin activity, as measured by the CSF concentrations of serotonin metabolites (rhesus macaques, Mehlman et al., 1994; dogs, Reisner et al., 1996). Therefore, serotonin-enhancing agents have been used to treat certain forms of aggression, particularly dominance-related aggression (Dodman et al., 1996a; Peremans et al., 2005).

Nonbehavior modifying effects: As discussed for the TCAs, antidepressants have been used for treatment of pain (Micó et al., 2006). However, the strongest evidence has been for TCA drugs, which have effects on neurotransmitters (norepinephrine, histamine, dopamine) other than serotonin. Although there is some evidence for an analgesic effect from SSRI drugs, it is not as convincing as for TCA drugs.

Adverse effects: In general, SSRIs have an excellent safety record. Adverse effects vary from agent to agent, but include gastrointestinal effects and nervous system alterations ranging from sedation to agitation, irritability, and insomnia. In a study of fluoxetine in dogs (Simpson et al., 2007) in which 122 dogs were treated with fluoxetine and 120 with placebo, the most common adverse effect was lethargy/depression/calming (45%). The second most common effect reported was anorexia/decreased appetite (29%). Gastrointestinal effects (up to 25% of humans) are likely due to the concentration of serotonin receptors in the GIT. SSRIs are considered to cause less effect on cardiac impulse conduction than TCAs (Pacher et al., 1999). Starting a patient at a low dose and then increasing after 1 week may reduce the likelihood of adverse events (Sherman, pers. obs.). Onset to action may be 1–4 weeks (Simpson et al., 2007). Because of its extended half-life, fluoxetine in humans (Zahajzky et al., 2009) and dogs (FDA, 2007) does not require dose tapering for discontinuation.

In people, there is great variation in the effect of SSRIs on CYP 450 enzymes. These differences have not been reported in animals. In people, fluoxetine, fluvoxamine, and paroxetine all inhibit one or more CYP enzymes; sertraline, citalopram, and escitalopram do not. But, as discussed in Section Absorption, Metabolism, Clearance, and Distribution, it is not known what CYP 450 enzymes are affected by these drugs compared to people because of the differences in enzymes and it is difficult to predict potential drug interactions. Drug interactions have been infrequently reported from administration of an SSRI to animals.

Fluoxetine

Fluoxetine (Prozac, and generic human label) is widely used to treat a range of human behavioral disorders, including depression, generalized anxiety, panic disorder, obsessive–compulsive disorder, eating disorders, and premenstrual dysphoria (Figure 18.4).

Among dogs, fluoxetine has been used for treatment of dominance-related aggression (Overall, 1999a; Dodman et al., 1996a), interdog aggression (Dodman, 2000), acral lick dermatitis (Rapoport et al., 1992; Wynchank and Berk, 1998a), anxiety and panic-like disorders, as well as other compulsive disorders (Irimajiri and Luescher, 2005). Fluoxetine has also been used to successfully treat stereotypical pacing (considered a compulsive disorder) of 22 years' duration in a captive polar bear; relapse occurred after discontinuation of treatment (Poulsen et al., 1996). Among cats, fluoxetine has been used for treatment of refractory urine spraying (Pryor et al., 2001), inappropriate urination (Romatowski, 1998), psychogenic alopecia (Hartman, 1995; Romatowski, 1998), and aggression (Overall, 1999b; Romatowski, 1998).

Fluoxetine is metabolized to norfluoxetine, its active metabolite. Norfluoxetine has an elimination half-life of 4–16 days in humans (Zahajzky et al., 2009). After a single dose in dogs, fluoxetine has an elimination half-life of 3–13 hours; norfluoxetine has an elimination half-life of 33–64 hours (Reconcile package insert, Lilly, 2007). This long half-life offers protection from the discontinuation syndromes associated with abrupt interruption or termination of treatment. It also necessitates a washout period after discontinuation of fluoxetine and initiation of a monoamine oxidase inhibitor such as selegiline (Zahajzky et al., 2009; Reconcile package insert, Lilly, 2007).

Because the approved canine form is no longer available, veterinarians use the human generic formulations.

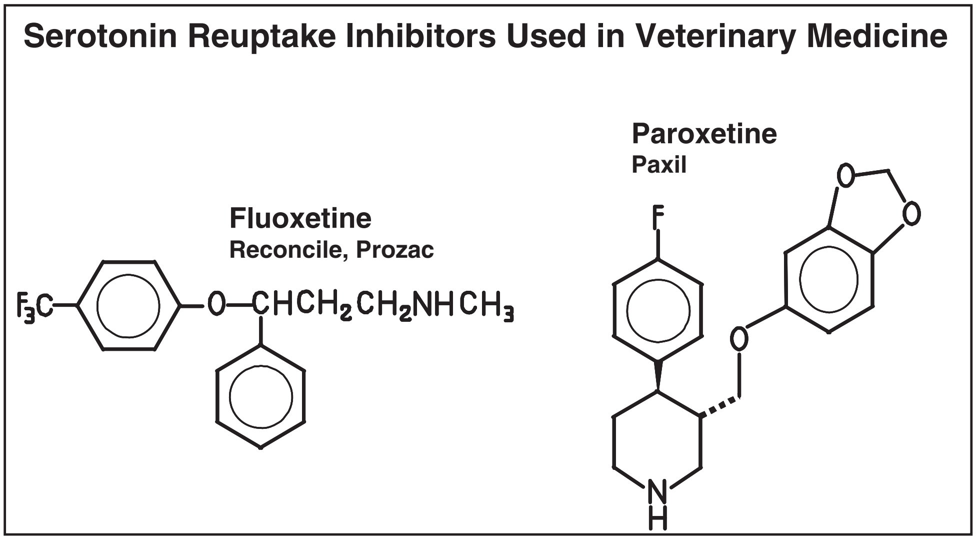

Figure 18.4 Selective serotonin reuptake inhibitors (SSRIs) used in veterinary medicine. Fluoxetine (left) and paroxetine (right). Only fluoxetine (Reconcile) has been licensed for veterinary use.

The 10 and 20-mg capsules must be divided or compounded for smaller animals, or 10 or 20-mg tablets that can be broken. There is a 4 mg/ml oral liquid solution, but it is mint flavored and has 0.23% alcohol, which some animals (especially cats) may find unpalatable. The usual dose for dogs is 1–2 mg/kg oral per day (Simpson et al., 2007); the dose for cats is 0.5–1.0 mg/kg oral per day (Landsberg et al., 2013; Pryor et al., 2001). Fluoxetine may require 1–4 weeks to effect.

In dogs the most common effects in clinical trials were sedation and calming effects, followed by anorexia and weight loss. Less common effects observed were vomiting, shaking, diarrhea, restlessness, vocalization, aggression, and, in rare cases, seizures. Treatment with fluoxetine in dogs for acral lick dermatitis was well tolerated (Wynchank and Berk, 1998b). In dogs and cats, inappetence is a common side effect (Pryor et al., 2001; Simpson et al., 2007); lethargy has been reported (Simpson et al., 2007; Hartman, 1995; Pryor et al., 2001); vomiting is rare (Pryor et al., 2001). Fluoxetine may decrease libido in breeding animals; higher doses of fluoxetine may cause serotonin effects in the intestine.

Paroxetine

Like fluoxetine, paroxetine is used in humans to treat a range of psychiatric complaints, including depression, social anxiety, and panic disorder (Figure 18.4) and has been considered by some to be the first choice for treatment of generalized anxiety (Baldwin and Tiwari, 2015).

In dogs, paroxetine may be helpful for the treatment of canine aggression and canine compulsive disorders but efficacy has not been documented as well as for fluoxetine. In cats, paroxetine has been used for compulsive behaviors, redirected aggression, and generalized anxiety. Paroxetine is available in 10, 20, 30, and 40-mg tablets that can be more easily divided than capsules and administered orally to cats.

Compared to fluoxetine, paroxetine has a shorter elimination half-life and reaches steady-state more rapidly in people. However, pharmacokinetics have not been fully reported for animals.

Compared to fluoxetine, anticholinergic side effects, such as dry mouth and constipation, are more common with paroxetine. Constipation is a common anticholinergic side effect of paroxetine use in cats. Cats should be carefully monitored for food and water consumption and urine and feces production during the first week of therapy. Reducing the target dose by half for the first week can avoid such side effects (Sherman, pers. obs. 2000–2006). Weight gain is a common side effect in cats with paroxetine treatment (Sherman, pers. obs. 2000–2006). To avoid negative metabolic consequences of weight gain, the body weight of cats receiving paroxetine treatment should be monitored closely. Paroxetine can cause an idiosyncratic, dose-dependent increase in arousal, wakening, and REM suppression in humans (Ehmke and Nemeroff, 2009) and dogs (Sherman, pers. obs. 2000–2016).

Other SSRIs

Sertraline is an SSRI with pharmacokinetic properties in humans similar to paroxetine. Like other SSRIs, in humans, it is used for a range of behavioral disorders including panic disorder, chronic depression, compulsive disorders, and anxiety (Sheikh et al., 2000). It is considered by some to be the first choice for treatment of panic disorder in humans (Baldwin and Tiwari, 2015) and may provide some cognitive benefits to elderly patients, compared to other SSRIs. Like other SSRIs, sertraline has been used as a treatment for eating disorders. In one report, sertraline was used to successfully treat chronic regurgitation, deemed to be a compulsive behavior in a chimpanzee (Howell et al., 1997). In dogs, **sertraline** (Block et al., 2009) can be helpful for compulsive behaviors (Rapoport et al., 1992), aggression (Larson and Summers, 2001), and anxiety disorders. Diarrhea is a common side effect, which may be circumvented by starting the drug at a low dose and increasing over 2 weeks.

Fluvoxamine (Aboujaoude and Kalin, 2009) is distinguished by its lack of activity in humans at CYP2D6 isozyme. Therefore in people it has been more safely combined with TCAs. However, the use of fluvoxamine is unreported for animals.

Citalopram (Roseboom and Kalin, 2009) was approved by the US FDA in 1998 for the treatment of depression in humans, after a long history of safe human administration in Europe (Pollock, 2001). Although early studies of citalopram administration to dogs at high doses (20 mg/kg) (Boeck et al., 1982) revealed no cardiac effects, one toxicity study of 10 beagle dogs given a high dose of citalopram (8 mg/kg/day) for 17–31 weeks suffered 50% mortality due to cardiac effects (Forest Pharmaceuticals Inc., 1998). Citalopram has been used to treat acral lick dermatitis in dogs at a dose of 0.5–1.0 mg/kg/day (Stein et al., 1998). Citalopram may modulate aggressive behavior in humans (Reist et al., 2003) and dogs. One study of impulsively aggressive dogs (N = 9) treated for 6 weeks with citalopram demonstrated behavioral improvement (Peremans et al., 2005). Based on the suggestion of increased cardiac sensitivity to citalopram particularly in beagle dogs, cardiac screening (Pacher et al., 1999) and conservative dosing, or alternative drug selection are recommended. To date, there are no published reports of the use of citalopram in cats.

The S-isomer of racemic citalopram, **escitalopram** (Lexapro, Forest Pharmaceuticals), may be promising for the treatment of behavioral disorders in dogs, but at this time, there is limited information. It is a potent and highly selective inhibitor of CNS neuronal reuptake of serotonin (Roseboom and Kalin, 2009). No published studies are currently available for its use in companion animals. It is now available as a generic, but future reports will be needed to determine efficacy in companion animals.

Other and Atypical Antidepressants

Serotonin and norepinephrine reuptake inhibitors (SNRIs) include venlafaxine and duloxetine (Thase and Sloan, 2009), among others. To date, they are uncommonly used in the treatment of behavioral disorders in companion animals (dogs and cats) and research on their effectiveness is lacking. Given their ability to affect both serotonin and norepinephrine reuptake, these have been used to treat pain syndromes, particularly neuropathic pain and fibromyalgia, but application in veterinary medicine has not been well characterized. The atypical antidepressants are a diverse category of heterocyclic drugs. These include trazodone (Desyrel), nefazodone (Serzone), bupropion (Welbutrin, Welbutrin XL, Zyban), and mirtazapine (Remeron). Because of its rare association in humans with life-threatening liver failure, nefazodone is now rarely prescribed. Buproprion has a stimulating effect, and does not sufficiently enhance behavioral calming in animals to be clinically useful. Discussed below are the other atypical antidepressants trazodone and mirtazapine.

Trazodone: Most notable in this group for clinical use in small animals is trazodone (Golden et al., 2009). Trazodone is a mixed serotonergic agonist/antagonist. It has no anticholinergic effects, moderate antihistaminergic activity, and is an antagonist of postsynaptic α_1-adrenergic receptors. Trazodone is well absorbed in humans and appears to have similarly rapid and complete oral absorption in animals. Trazodone is bioavailable after oral administration in dogs, though variation exists in time to maximum plasma concentrations (Jay, 2013). Pharmacokinetic data is not available in cats, but behavioral effects may be seen fairly rapidly following oral administration in cats (Orlando, 2016), and plasma concentrations were achieved that were in the range produced in dogs and humans.

In humans, the cytochrome isozyme CYP2D6 is involved in the metabolism of trazodone and caution is advised when prescribing trazodone with SSRIs that inhibit CYP2D6 (Golden et al., 1998). However, the wide safe dose range for trazodone makes this less problematic than other drugs, such as the TCAs. Trazodone is used in humans for treatment of major depression and to counter the sleep disturbances caused by SSRIs. When given over weeks, it produces anxiolytic properties similar to diazepam (Golden et al., 1998). An extended-release formulation of trazodone (Oleptro) is now available for treatment of depression in humans, but has not been evaluated in animals.

Trazodone has been used in dogs for mild thunderstorm phobia (Gruen and Sherman, 2012) and as an adjunct to TCA or SSRI treatment (Gruen and Sherman, 2008). However, trazodone may have some limitations. In one study of four “depressed” laboratory beagles, no effect was noted after administration of trazodone at a high dose (10 mg/kg; Iorio et al., 1983); its effects appear insufficient in severe cases of thunderstorm phobia (Sherman, pers. obs. 1997–2002). Side effects in dogs include sedation and GIT issues, including vomiting and diarrhea (Sherman, pers. obs. 1997–2002), particularly during the first few days of dosing. Starting at a low dose and titrating the dose up over the initial days and subsequent weeks may be helpful (Gruen and Sherman, 2008). Priapism, noted as a rare side effect in human males, has not been observed in neutered male dogs (Sherman, pers. obs. 1997–2007).

Trazodone may be used in combination with antidepressants, particularly SSRIs, to enhance behavioral calming, decrease agitation, and to aid with sleep. This can be helpful in humans with depression, obsessive–compulsive disorder, and other anxiety disorders (Stahl, 2013). It may be similarly effective in dogs (Gruen and Sherman, 2008). Trazodone has also been shown to be effective in facilitating behavioral calming in dogs following elective orthopedic surgeries (Gruen et al., 2014) and in cats for travel anxiety and veterinary examinations (Stevens et al., 2016).

Mirtazapine: Mirtazapine (Remeron) exhibits noradrenergic and serotonergic activity through its activity as an α_2 antagonist. In humans, it is used to manage depression and anxiety. Mirtazapine is a potent antagonist of histamine H_1 receptors, which may account for its sedative effects. The antagonism of $5HT_3$ receptors by mirtazapine results in an antiemetic effect, suggesting that mirtazapine could be considered a successful antiemetic agent in patients suffering from nausea and vomiting. Although uncommonly used for the treatment of primary behavior problems in animals, it has recently found safe and useful application in the management of anorexia in dogs and cats. Elimination half-life in dogs ranges from 20 to 40 hours and reaches a steady-state in 4–6 days.

The most common use of mirtazapine has been for appetite stimulation in cats, particularly cats with chronic kidney disease (CKD). The appetite-stimulating effects are attributed to the $5HT_3$ antagonist properties; therefore, it may share similar effects as antiserotonin medications used for antiemetic uses. Mirtazapine has been studied more in cats than in dogs (Quimby and Lunn, 2013). These studies in cats have shown that it is an effective appetite stimulant. The dose is usually 1.88 mg per cat oral. At high doses it produces adverse effects that include vocalization and increased restlessness. In cats it has a half-life of approximately 10 hours, which allows for once-daily dosing. In cats with chronic kidney disease – for which appetite stimulation often is desired – clearance is slower and the half-life increases to 15 hours, which indicates that an every-other-day dosing schedule of 1.88 mg per cat should be used in cats with kidney disease to avoid accumulation (Quimby et al., 2011). Mirtazapine is available as 7.5-mg tablets, but also is available in 15, 30, and 45-mg sizes. The formulation that some veterinarians prefer is a rapidly disintegrating oral tablet that dissolves easily in an animal's mouth (15, 30, and 45 mg).

Monoamine Oxidase Inhibitors

Monoamine oxidase inhibitors (MAOIs) are drugs that inhibit the intracellular enzyme monoamine oxidase (MAO) (Krishnan, 2009). Since MAO catabolizes intracellular monoamine neurotransmitters, such as serotonin, dopamine, norepinephrine, and tyramine, MAOIs inhibit this process, causing an increase in monoamines. There are two MAO subtypes, A, which affects serotonin, dopamine, norepinephrine, and tyramine, and B, which affects the metabolism of phenylethylamine as well as dopamine. Location of the enzymes also characterizes the differences between type A and B. Type A is located in the intestine as well as the CNS. If MAO-type A is inhibited, it can produce a decrease in the metabolism of compounds from foods that can produce systemic effects. However, this effect has not been well characterized in animals, perhaps because of the rare clinical use of these drugs.

Selegiline

The nonselective (Type A and B) MAO-inhibitors are not used to any extent in veterinary medicine. Only one MAO-B inhibitor, selegiline (L-deprenyl, Anipryl), is clinically important as a behavioral treatment in animals. Selegiline is approved by the FDA for treatment of canine cognitive dysfunction, a disorder of elderly dogs characterized by decreased social interactions, loss of house-training, confusion, and changes in sleep cycle (Milgram et al., 1993; Ruehl et al., 1995). There is evidence that these behavioral changes have a histolopathological (Cummings et al., 1996) and metabolic (Milgram et al., 1993) basis and selegiline may affect these changes. However, at currently registered doses for dogs, it has not produced beneficial effects on anxiety or depression and is generally not used for this purpose by veterinary behavior experts in the United States.

The action of selegiline is to inhibit MAO type B (and other MAOs at higher doses). Studies in dogs showed that MAO inhibition was specific at doses of 1 mg/kg (Milgram et al., 1993, 1995). The proposed mechanism of action of this drug is to inhibit the metabolism of dopamine in the central nervous system (Bruyette et al., 1995). The theory to explain the beneficial response is that dopamine depletion in the brain and loss of dopaminergic neurons leads to cognitive dysfunction (dementia) in old dogs. Treatment with selegiline increases dopamine concentrations in the brain, which restores neurotransmitter balance and improves cognitive ability. It also inhibits the metabolism of phenylethylamine (Milgram et al., 1993, 1995). Phenylethylamine in laboratory animals produces amphetamine-like effects. There are two active metabolites of selegiline, L-amphetamine and L-methamphetamine. In dogs, even though there were increases in amphetamine concentrations (Milgram et al., 1993), they were not high enough to produce adverse effects. However, at high doses (>3 mg/kg) the authors proposed that increased amphetamine concentrations could explain the observed behavioral changes. The L-isomer metabolites are not as active as their D-forms and studies have not supported a potential for amphetamine-like abuse or dependency from selegiline, compared to other amphetamine-like drugs.

In clinical trials, selegiline significantly improved clinical signs of cognitive dysfunction in treated dogs compared to controls. Selegiline may also improve learning (Mills and Ledger, 2001). In general, selegiline is given daily for a month. Any improvement in clinical signs dictates continuation of treatment; additional improvement is often seen in subsequent months (Calves, 2000). Treatment failure should prompt an increase in daily dose and an additional trial of medication. As an extralabel application, selegiline has also been used in geriatric cats diagnosed with cognitive dysfunction.

Side effects are uncommon, but high doses can cause hyperactivity and stereotypic behavior in dogs. In studies in dogs in which selegiline was administered a doses of 1, 4, or 16 mg/kg for 1 year, adverse effects were rare. At high doses salivation, panting, repetitive movements, decreased weight, and changes in activity level were noted. In one report (Milgram et al., 1993), changes in behavior were not seen until doses exceeded 3 mg/kg, which the authors attributed to amphetamine-like effects.

Selegiline is also FDA-approved for treating canine pituitary-dependent hyperadrenocorticism (PDH). The mechanism of action to explain selegiline's effect for treating PDH is potentiation of dopamine. Increased dopamine levels in the brain decreases ACTH release, resulting in lower cortisol levels (Bruyette et al., 1995, 1996). Blockade of dopamine enhances CRH-mediated ACTH release in normal dogs. In 52 dogs with PDH, administered selegiline at 1.0 mg/kg once daily, there was significant improvement in polyuria–polydipsia, appetite, activity, thinning of skin and alopecia, body weight, and body conformation (Bruyette et al., 1996). There was also a significantly lower mean response in the low-dose dexamethasone suppression test. Overall, selegiline was evaluated as effective in 71% of dogs and not effective in 21%. Side effects of therapy were rare. However, other studies released after the drug's FDA approval have not been as convincing. In one study, the authors found a much smaller percentage of PDH dogs that responded to selegiline and they did not recommend this drug for treatment (Reusch et al., 1999). It has been proposed that only dogs with *pars intermedia* lesions of the pituitary will respond to selegiline, which represents 30% or less of canine PDH cases (Peterson, 1999).

MAOIs can sufficiently inhibit catabolism of monoamines that their concentration, particularly serotonin, becomes toxic. This may occur when other antidepressants that inhibit reuptake of serotonin or inhibit MAO are used concurrently. This can lead to serotonin syndrome, a potentially fatal condition, characterized by hypertension, hyperthermia, restlessness, tremor, seizures, and altered mental status (Calves, 2000; Krishnan, 2009; Wismer, 2000). Thus, an MAOI should not be used with an antidepressant, including TCAs (Anderson, 2001) and SSRIs. Drugs from one class should be discontinued 14 days before agents from the other class are initiated (Anderson, 2001). Tricyclic antidepressants and selective serotonin reuptake inhibitors should not be used concurrently with other MAOI such as amitraz, a topical product used for control of ticks and mites.

Because selegiline may affect other monoamine synthesis, there has been concern about its administration with sympathetic amines used to treat urinary incontinence in dogs, such as phenylpropanolamine. However, when this was studied, selegiline had no effect on pulse rate, ECG, or behavior compared to administration of phenylpropanolamine alone in dogs (Cohn et al., 2002).

Concurrent use of α_2 agonists, phenothiazines, and opiate analgesics is discouraged with selegiline. A standard recommendation is to wait at least five times the elimination half-life of the SSRI or its active metabolite (whichever is longer), before administering the next serotonergic agent (Tollefson and Rosenbaum, 1998). A washout period of 1–3 weeks is recommended after discontinuation of an MAOI and initiation of another drug that affects monoamines.

Miscellaneous Drugs

Anticonvulsant Drugs

Anticonvulsants are covered in more detail in Chapter 17. However, they are mentioned briefly here because some anticonvulsants have been used to manage veterinary behavior problems. Some maladaptive behaviors, such as tail chasing and unprovoked rage aggression in Bull Terriers, have been postulated to be partial complex seizures at least in part due to their positive response to phenobarbital (Crowell-Davis et al., 1989; Dodman et al., 1992, 1996b). In other cases with similar presentations, phenobarbital treatment is ineffective (Brown et al., 1987). Response may be obtained with narcotic antagonists (Brown et al., 1987) or anticompulsive agents (Hewson, 1998b).

Other applications exist for the behavioral use of anticonvulsants. Carbamazepine (Tegretol) has been used for the treatment of aggression in two cats (Schwartz, 1994) and for treatment of aggression (Carter, 2008) and psychomotor seizures in a dog (Holland, 1988). Since blood dyscrasias may result (at least in humans), regular evaluation of the CBC is recommended for patients given carbamazepine. New anticonvulsants, such as gabapentin (Neurontin), topiramate (Topamax), lamotrigine (Lamictal), and tiagabine (Gabitril), show promise for management of anxiety disorders and other behavioral disturbances. Gabapentin, in particular, is used for treatment of anxiety in both dogs and cats, and may be particularly useful when concerns exist about underlying pain.

Opiates

Opiates are presented in more detail in Chapter 13. Stereotypic, compulsive behaviors, such as self-traumatic licking, tail chasing, and pacing, are seen in animals confined to zoos and laboratory settings (Kenny, 1994). It has been postulated that such behaviors are "coping strategies" that lead to release of endogenous opiates (endorphins). Some cases of dogs and other animals have been successfully treated with the oral narcotic antagonist naltrexone (Brown et al., 1987; Dodman et al., 1988; Kenny, 1994; White, 1990) or other opiate antagonists (Dodman et al., 1988). Horses with "crib biting" have also been treated with opiate antagonists.

There is evidence that there may be a developmental component to the expression of stereotypies (Kennes et al., 1988). Other cases of client-owned dogs develop acral lick dermatitis associated with repetitive licking for unknown reasons (Dodman et al., 1988; White, 1990). Since the etiology of stereotypic behavior (based on response to treatment) is uncertain, treatment with anticompulsive (Hewson et al., 1998b) or anticonvulsant (Dodman et al., 1992) agents should also be considered in such cases.

Hormonal Therapy

Reproductive hormones are discussed in more detail in Chapter 27. Historically, synthetic progestins have been used to treat a wide range of behavioral disorders. Most likely the response to these drugs is caused by their mild sedating effects on steroid receptors in the CNS (McEwen et al., 1979). This nonspecific use has declined with the advent of more specific agents, described in this chapter. The use of progestin hormones for behavioral therapy is now considered a "last resort" therapy to avoid abandonment or euthanasia of the offending animal.

In castrated and entire male dogs, megestrol acetate (Ovaban) has been used for the treatment of dominance-type (Borchelt and Voith, 1986) and intermale aggression, mounting, urine marking, and tendency to roam (Joby et al., 1984). In one study of 123 males, 75% improved with hormone treatment (Joby et al., 1984). Side effects included increased appetite and lethargy. Relapse within 3 months was most common in dogs that had signs of dominance-type aggression and marking (Joby et al., 1984). However, such treatment significantly impairs adrenocortical function as measured by ACTH stimulation during treatment (van den Broek and O'Farrell, 1994).

In cats, megestrol acetate may reduce the incidence of aggression (Henick et al., 1985; Marder, 1993) and urine spraying, particularly among neutered male cats (Hart, 1980). Side effects of progestins in cats include hyperphagia, obesity, hyperglycemia leading to diabetes, lethargy, mammary gland hyperplasia and adenocarcinoma, pyometra, and bone marrow suppression (Romatowski, 1989; Henik et al., 1985).

Another class of drugs that has been used in male animals for treatment of behavior problems are long-acting progestins. Medroxyprogesterone acetate (DepoProvera) is the most common of this group. It has a long-acting depot effect after a single injection that may last several days up to 3–4 weeks. A dose that has been used is 10–20 mg/kg, injected SC or IM. This drug may be as effective as megestrol acetate for some indications. Medroxyprogesterone acetate (Depo-Provera) has been used in cats for urine spraying in a manner similar to that of megestrol acetate (Hart, 1980).

Reproductive hormones have been used in postmenopausal women in combination with a first-line SSRI to enhance therapeutic effects (Stahl, 2013). Although controlled clinical trials are not available, clinicians anecdotally report benefits. Such a strategy may be helpful in spayed female dogs with refractory behavioral problems, although no published reports are currently available.

Thyroid hormones are discussed in Chapter 28. Thyroid hormones have been used to accelerate (Altshuler et al., 2001) or augment (Stahl, 2013) TCA response, particularly in women. Thyroid supplementation may increase cortical 5HT concentrations and desensitize autoinhibitory $5HT_{1A}$ receptors in the raphe area, resulting in disinhibition of cortical and hippocampal 5HT release (Altshuler et al., 2001). Mixed reports exist about the association between thyroid hormone concentrations and the effect of thyroid supplementation in dogs with aggression.

Melatonin is produced by the pineal gland according to the light/dark cycle, with light acting as a production suppressant. The nocturnal secretion of melatonin is primarily induced by increased noradrenergic neurotransmission, resulting in increased activity of the rate-limiting enzyme that converts serotonin to melatonin. In recent years, melatonin has become a popular over-the-counter remedy for insomnia in humans and behavioral calming in dogs, although data on safely, efficacy, or appropriate doses are not available (Stahl, 2013). Melatonin given with amitriptyline was used in one dog to improve signs of generalized anxiety disorder (Aronson, 1999).

Melatonin is an endogenous hormone, produced from serotonin in the pineal gland. At high doses in dogs (1–1.3 mg/kg q 12 h), melatonin affects endogenous sex hormones, but does not affect prolactin or thyroid concentrations in adult dogs (Ashley et al., 1999). Melatonin has been used with amitriptyline to manage thunderstorm phobia (Aronson, 1999), since it impairs psychomotor vigilance (Graw et al., 2001). No controlled studies on the behavioral effects of melatonin on dogs have been conducted.

Beta-Blockers

The beta-adrenergic antagonist propranolol (Inderal) has been used to ameliorate the sympathetic symptoms of anxiety in humans, including trembling, sweaty palms, and tachycardia (reviewed in Steenen et al., 2016) and to treat organically based aggression (Williams et al., 1982). No controlled studies have investigated the efficacy of beta-blockers for treatment of anxiety disorders in small animals (Shull-Selcer and Stagg, 1991).

Pindolol is a beta-adrenergic blocker that is also an antagonist and partial agonist at $5HT_{1A}$ receptors. Pindolol may disinhibit serotonin neurons and may serve as a useful adjuvant therapy (Stahl, 2013).

In Great Britain, propranolol is used in combination with phenobarbital to manage phobic behavior (Walker et al., 1997). When propranolol is used in combination with the antipsychotic thioridazine, thioridazine plasma levels increase.

A beta-blocker with $5HT_{1A}$ autoreceptor antagonist properties, pindolol, may disinhibit serotonin neurons and may serve as a useful adjuvant therapy to TCAs (Altshuler et al., 2001; Stahl, 2013). However, in one study, pindolol was not superior to placebo for augmenting the effects of paroxetine of social anxiety symptoms (Stein et al., 2001).

Alpha$_2$ Agonists

These drugs are discussed in more detail in Chapter 14. The α_2-adrenergic agonists may be used for pharmacological behavioral management. Detomidine and dexmedetomidine, widely used for sedation via parenteral routes in animals, have significant behavioral effects when used via oral transmucosal (OTM) administration. Because of high first-pass metabolism effects these agents are not be active when swallowed.

Detomidine gel is marketed for OTM use in horses (Dormosedan Gel, Zoetis), particularly as a sedative and analgesic for standing procedures (l'Ami et al., 2013). When given in the buccal pouch of laboratory dogs, the equine formulation of detomidine (0.35 mg/m^2 OTM) has been shown to produce sedation, reduce anxiety, and facilitate handling in laboratory dogs (Hopfensperger et al., 2013). Side effects included transient bradycardia but no respiratory depression.

Dexmedetomidine has been given via OTM route to dogs (Cohen and Bennett, 2015) and cats (Santos et al., 2010) for procedural sedation. The injectable formulation of dexmedetomidine (Dexdormetor, Zoetis) was administered in the buccal pouch to dogs (N = 4, mean dose 32.6 μg/kg body weight), resulting in satisfactory sedation for restraint, and subsequently reversed with atipamezole. OTM dexmedetomidine (20 μg/kg) plus buprenorphine (20 μg/kg) were used to sedate 87 shelter-owned cats for catheter placement (Santos et al., 2010). In this study, 25% of the cats required additional use of IM ketamine to facilitate catheterization.

Recently, dexmedetomidine gel has been formulated for OTM administration in dogs and is now approved by the FDA to attenuate fear and/or anxiety elicited by specific noises, such as the sound of fireworks (Sileo, Zoetis). The recommended dose, given 30–60 minutes prior to the inciting noise, is 125 μg/m^2 OTM, with redosing after 2 or more hours. In a double-blinded, placebo controlled clinical trial (N = 144 dogs), 75% of owners whose dogs received Sileo rated the treatment effect to be good or excellent (FOI information, Sileo). Published data for the Sileo oral gel product is not available for cats. However, oral transmucosal administration of dexmedetomidine has been used in cats at a dose of 40 μg/kg and was safe and effective. It produced similar sedative and antinociceptive properties as the parenteral administration (Slingsby et al., 2009).

The centrally acting α agonist clonidine is used in human medicine as an antihypertensive agent, and to target behavioral signs associated with hyperactivity, hypervigilance, impulsivity, and posttraumatic stress syndrome (Strawn and Geracioti, 2008). Clonidine blocks norepinephrine release through activation of α_2 receptors on presynaptic neurons in the locus ceruleus. In dogs, clonidine has been used orally to manage fear-based problems in dogs, often in combination with other serotonergic agents. In one open trial of 22 client-owned dogs, 82% of clients reported positive effect with the addition of clonidine (Ogata and Dodman, 2011). The dose range was 0.007–0.049 mg/kg PRN up to twice a day PO; some patients also received clomipramine, fluoxetine, sertraline, or buspirone (Ogata and Dodman, 2011).

Tramadol

Tramadol is discussed more in Chapter 13. Tramadol has three effects that may act synergistically: opiate agonist, inhibition of synaptic reuptake of norepinephrine, and inhibition of synaptic reuptake of serotonin. The latter two effects resemble the action of tricyclic antidepressants discussed earlier in this chapter. With respect to efficacy of tramadol for some conditions – including behavior problems – perhaps equal or greater importance than opiate agonistic activity is the effect on serotonin and norepinephrine reuptake. One of the stereoisomers is more prominent at inhibiting serotonin reuptake and the other isomer has more of an effect on norepinephrine reuptake. Some studies in experimental animals and people with tramadol have elicited significant behavior-modifying effects. However, veterinary clinical studies for this use are lacking.

Analgesia may also play a role in the action of this drug for some behavior problems. Veterinary behaviorists are often faced with uncertainty about the role of pain in the presentation of a behavior problem. Older animals or those with chronic degenerative orthopedic diseases may be irritable, leading to anxiety or irritable aggression. Although a thorough physical examination and appropriate diagnostic tests are indicated, the role of pain may remain uncertain. Often, a trial of analgesics may be initiated as a way to determine if pain management improves behavior. In addition to the many new nonsteroidal agents discussed in Chapter 20, tramadol also may be useful, alone or in combination with other behavioral drugs.

Nutraceuticals

A range of products often called nutraceuticals, natural products, or dietary supplements are marketed for treatment of behavior disorders in dogs and cats and are available to pet owners without a veterinarian's prescription. These products may be used alone or in combination with pharmaceutical therapy. The most common applications in dogs and cats are for management of fear and anxiety, and for management of cognitive dysfunction. Briefly summarized here are commercially available products with efficacy supported by one or more studies in companion animals.

Natural products used to treat fear and anxiety include amino acids, plant proteins, and milk proteins. L-theanine, is an analogue of the amino acid L-glutamate. It is considered safe by the FDA and is found primarily in particular plant and fungal species, including green tea. A veterinary formulation (Anxitane, Virbac Animal Health) has been shown to reduce fear of humans in laboratory dogs (Araujo et al., 2010) and to reduce fear responses to thunderstorms in client-owned dogs (Pike et al., 2015). Another product, combining extracts from plants *Magnolia officinalis* and *Phellodendron amurense* (Harmonese, Vet Products Labs) has been shown to reduce anxiety associated with thunderstorm sounds in laboratory dogs (DePorter et al., 2012). α-casozepine, a lactose-free milk protein (Zylkene, Vetoquinol) has been shown to reduce signs of anxiety-related disorders in cats (Beata et al., 2007a) and dogs (Beata et al., 2007b). In one blinded study, there was no difference in efficacy between α-casozepine and the monoamine oxidase inhibitor selegiline (Anipryl) for treatment of anxiety disorders in dogs (Beata et al., 2007b).

Combinations of these products are commercially available. One product combines L-theanine, colostrum complex, and thiamine (B1) (Composure, VetriScience); another combines L-theanine, *Magnolia officinalis*, *Phellodendron amurense*, and whey milk protein (Solliquin, Nutramax Labs). Clinical studies of these products are not available; anecdotal reports suggest that they are well tolerated by dogs and cats (Sherman, personal communication, 2016).

Natural products are marketed for management of age-related cognitive dysfunction. These include *S*-adenosylmethionine (SAMe) (Novifit, Virbac Animal Health). SAMe is an endogenous metabolite involved in several biochemical pathways, and is deficient in humans with Alzheimer's disease. In a laboratory study of aged dogs and cats treated with SAMe, dogs showed measurable reduction in learning errors but no treatment effects on memory (Araujo et al., 2012). Cats with relatively low levels of cognitive impairment showed a reduction in learning errors with treatment but cats with high levels of impairment showed no such beneficial effects. The results suggested treatment early in the disease course may be most effective (Araujo et al., 2012).

Apoaequorin, a calcium-buffering protein obtained from jellyfish (Neutricks, Neutricks LLC), enhanced operant learning in aged dogs with signs of cognitive dysfunction (Milgram et al., 2015). Another product that combines agents *Ginkgo biloba*, phosphatidylserine, D-α tocopherol, and pyridoxine, suggested to have neuroprotective properties on age-related brain neurodegenerative changes (Senilife, Ceva Animal Health). In one study, administration of Senilife to geriatric dogs reduced the frequency of behaviors associated with canine cognitive dysfunction (Osella et al., 2007).

Drug Combinations

Combined Use of Behavioral Drugs

When the effect of one drug is inadequate, a second drug may be added. In fact, this strategy is utilized in commercially available combination products, such as the combination of olanzapine (an antipsychotic) and fluoxetine (an SSRI) marketed by Lilly under the trade name Symbyax, approved by the FDA for treatment of bipolar depression in humans (Eli Lilly, 2017). One strategy is to start with an antidepressant, such as a TCA or SSRI. Then, if needed, a benzodiazepine (Ibanez and Anzola, 2009), trazodone (Gruen and Sheman, 2008), or other agent may be added. A cautious approach is to add the second agent at a low dose, and then titrate the dose to a therapeutic level as response is monitored. Failure to sufficiently manage severe behavior problems, such as separation anxiety, can lead to animal relinquishment and even euthanasia, so aggressive treatment, in combination with behavior modification, may be necessary.

Treatment Success

In each case to which psychotropic medication is administered, there must be a means of documenting treatment response. The first step is to determine target signs that can be documented by the client with regard to frequency, intensity, and duration. The second step is to document the occurrence of these signs over time. Treatment response is often defined as 50% or greater improvement in symptoms.

Clients must also be educated as to probable side effects and duration to effect. Many behavioral drugs will produce side effects within hours or days of first administration, but may require weeks to onset of desired behavioral effects.

The duration of treatment has not been systematically investigated. One strategy is to continue treatment for 2 months after satisfactory treatment response, and then gradually decrease the dose over weeks. If the status quo is maintained, the drug can be discontinued. If treatment success wanes, the previous dose should be reinstated for an additional 6 months and the process repeated.

With the exception of clomipramine (Clomicalm), fluoxetine (Reconcile), and selegiline (Anipryl), the behavioral drugs discussed here are not approved by the FDA for animal use. The limitations and risks of extralabel prescribing should be explained to the pet owner (Simpson and Voith, 1997; Papich and Davidson, 1995). An evaluation of the medical and behavioral history, a physical and neurological examination, and appropriate laboratory tests should precede prescribing any psychotropic agent, and should be repeated at reasonable intervals during treatment. The risk associated with treating animals aggressive to people, especially children, should be carefully considered (Baumgardner, 1997). Patients should be monitored at regular intervals.

Summary

Behavioral pharmacology plays an increasingly important role in veterinary medicine. Drugs traditionally categorized as anxiolytics, antidepressants, anticonvulsants, and hormones may be used to help manage a range of animal behavior problems. Nutraceuticals offer an opportunity for first-line or adjunctive use, and are worthy of more research to determine efficacy in dogs and cats. Knowledge of how these agents act in the body and interact with other agents is imperative for safe, efficacious use.

Section 4

Autacoids and Antiinflammatory Drugs

19

Histamine, Serotonin, and their Antagonists

Wolfgang Bäumer

The author thanks H.R. Adams for the original chapter upon which this is based.

Histamine

Research on the effects of histamine (2-[4-imidazole]-ethylamine) began more than 100 years ago (Dale and Laidlaw, 1910) and is still not losing its attraction. Rather, histamine has been described as one of the most extensively researched molecules in the field of medicine (Akdis and Simmons, 2006). The first descriptions of histamine actions were contraction of smooth muscle and lowering of blood pressure. In these early publications, histamine was extracted from ergot extract contaminated with histamine-synthesizing bacteria. At the end of the 1920s, histamine was isolated from mammalian tissue and a direct connection to allergic-inflammatory reactions was discovered. Further characterization of histamine action was made possible by the discovery of specific histamine receptor antagonists. The early antagonists were mainly H_1 receptor blockers but it became obvious that these antagonists could not block all histamine actions. This led to the discovery of further histamine receptors (H_2 and H_3 receptors) and in 2000 the latest of the histamine receptors, the H_4 receptor, was cloned and characterized, breaking new ground in histamine research (Skidgel et al., 2011).

Mainly through H_1 receptor (and partly through the H_4 receptor), histamine is involved in anaphylaxis, inflammations and allergies, and certain types of adverse drug reactions. Using the second type of receptor (H_2), it regulates gastric secretion (Morris, 1992). The H_3 receptors modulate neurotransmitter release from neurons (Sander et al., 2008), whereas H_4 receptors participate in inflammation involving modulation of chemotaxis and cytokine secretion of eosinophils, T cells, and antigen-presenting cells into the site of inflammation (Zampeli and Tiligada, 2009). Both, the histamine H_1 and H_4 receptors are involved in the mediation of pruritus (itch) induced by histamine (Rossbach et al., 2011; Kollmeier et al., 2014). Histamine itself is not used therapeutically, but histamine receptor blocking agents (acting as histamine receptor inverse agonists) are commonly used to inhibit effects of endogenous histamine (MacGlashan, 2003).

Sources, Synthesis, and Metabolism of Histamine

Histamine is formed by the decarboxylation of the amino acid L-histidine by the enzyme histidine decarboxylase. Thus, this enzyme is present in all cell types that contain or synthesize histamine.

Histamine is widely distributed throughout mammalian tissue, but concentrations vary considerably in different species; for example quantities of circulating histamine are relatively high in the goat and rabbit but low in the horse, dog, cat, and human. Most of the histamine stored within the body is derived locally from enzymatic decarboxylation of L-histidine. Two general stores of histamine can be identified in mammalian species: the mast cell pool made up of mast cells in tissue and basophils in the blood. The non–mast-cell pool is localized in the gastrointestinal (GI) tract, central nervous system (CNS), skin, and other organs. These two pools differ not only in cellular composition but also in responsiveness to physiological and pharmacological stimuli.

The mast cell pool of highly concentrated histamine is distributed in connective tissue throughout the body. Circulating basophils, free counterparts of fixed-tissue mast cells, also contain high concentrations of histamine and are grouped with mast cells because of basic similarities. Within these two cell types, histamine is synthesized rather slowly and stored tenaciously in secretory granules; hence, the turnover rate is low. Because of the slow turnover rate, mast cell stores are replenished slowly after exposure to a histamine-releasing agent. The mast cell pool represents the histamine that participates in inflammatory responses, allergic phenomena, shock, some adverse drug reactions, and other forms of cellular insult.

Veterinary Pharmacology and Therapeutics, Tenth Edition. Edited by Jim E. Riviere and Mark G. Papich.

Companion Website: www.wiley.com/go/riviere/pharmacology

The precise cellular localizations and physiological functions of the non–mast-cell pool of histamine within the gastric mucosa, brain, and skin are still being identified. Histamine in the stomach mucosa – the source of stimulation of acid secretion on H_2 receptors of the gastric parietal cells – is derived from the enterochromaffin-like cells. Histamine in these regions, in contrast to the mast cell pool, undergoes a rapid turnover rate; it is synthesized and released continuously rather than being stored. Portions of this newly synthesized or nascent histamine are present within neural elements, and histamine acts as a neurotransmitter in the CNS. In the gastric mucosa, a "local hormone" action of histamine controls acid secretion.

Histamine's pharmacological actions are brief because of rapid metabolism and distribution into tissues. Biotransformation of histamine involves methylation and oxidation, as shown in Figure 19.1. For most tissues and species the more important is ring methylation to form *N*-methylhistamine catalyzed by the enzyme histamine-*N*-methyltransferase. Most of this metabolite is oxidized to methylimidazole acetic acid by the enzyme monoamine oxidase B. The second pathway is oxidative deamination catalyzed by the enzyme diamine oxidase (histaminase) to form imidazoleacetic acid, which is conjugated with ribose as riboside. Only a small percentage of the primary amine can be acetylated in the GI tract, absorbed, and excreted in urine. Trace amounts of free histamine is also excreted in urine.

Histamine Release

Histamine is highly concentrated in mast cell granules, where it is stored with a heparin–protein complex, proteolytic enzymes, and other autacoids. Release of histamine basically is a two-step process: sudden exocytotic extrusion of granules from the cell and release of histamine from the granules into the interstitial milieu. The latter occurs as an ionic exchange reaction between extracellular cations and molecules of granular histamine. Release can be initiated by a variety of stressful stimuli, including anaphylaxis-allergy, different drugs and chemicals, and physical injury.

Anaphylaxis and Allergy

Hypersensitivity phenomena associated with antigen–antibody reactions evoke active release of histamine from the mast cell pool (type I or immediate hypersensitivity). Free histamine then plays an important role in mediating physiological manifestations of such reactions as vasodilation, itching, smooth muscle contraction, and edema. Other autacoids also participate in tissue responses to hypersensitivity reactions. Signs of histamine involvement in systemic anaphylaxis vary in different species. In carnivores, histamine and anaphylaxis produce pronounced hypotension and hepatomegaly. In rabbits, pulmonary arterioles constrict and the right heart dilates in response to either histamine injection or exposure of a sensitized individual to the appropriate antigen. In

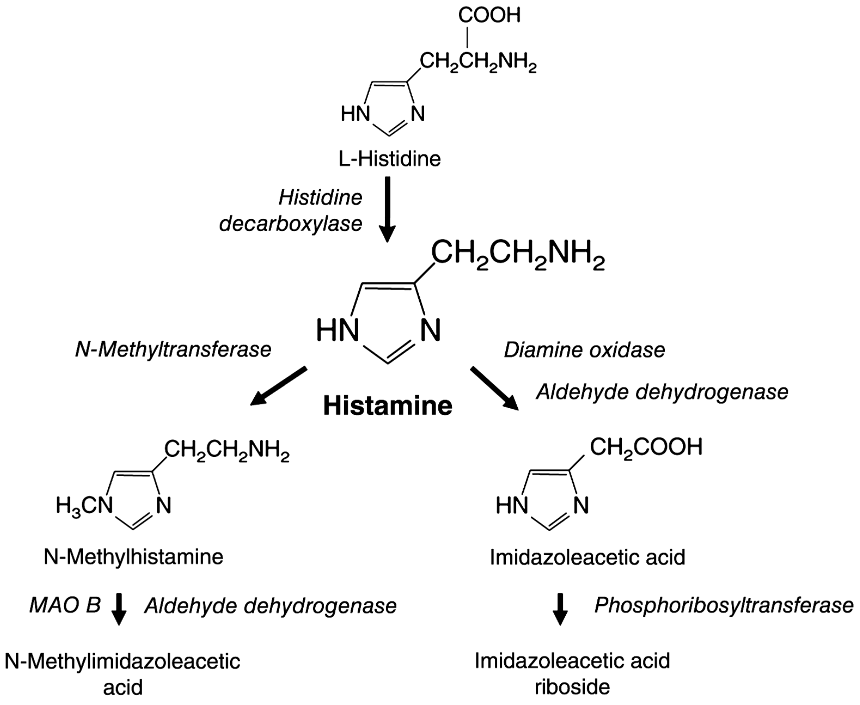

Figure 19.1 Synthesis and metabolism of histamine. Histamine is synthesized from L-histidine by decarboxylation. There are two major metabolizing pathways for histamine. The *N*-methylation of the ring followed by oxidative deamination and the oxidative deamination followed by conjugation with ribose. There seems to be tissue and species specific differences in which pathway is more pivotal; generally the *N*-methylation occurs more often. MAO, monoamine oxidase.

guinea pigs, dominant manifestations are bronchial constriction and death by asphyxiation. Humans seem to respond like guinea pigs and dogs in that severe hypotension, bronchial constriction, and laryngeal edema are principal signs of anaphylaxis.

The mast cell pool of histamine represents a major target for acute types of hypersensitivity-allergy reactions. As part of the allergic reaction to an antigen, IgE antibodies are generated which bind to the high affinity IgE receptor (FCεR1) on mast cells. Upon reexposure of the antigen, a crosslinking of two or more IgE molecules induces a signaling cascade involving tyrosine kinases and phosphorylation of several protein substrates within seconds leading eventually to a mobilization of intracellular calcium, which triggers the exocytosis of contents of secretory granules. Recent findings implicate, that the degranulation and secretion of proinflammatory mediators (cytokines/chemokines and leukotrienes) can be regulated by the affinity of the antigen to the specific IgE antibodies bound to the FCεR1 (Suzuki et al., 2014).

Release is an active process, requiring metabolic energy as well as Ca^{2+}, and should be distinguished from simple release secondary to cell destruction and cytolysis.

The ubiquitous cyclic adenosine 3′,5′-monophosphate (cAMP) system is involved in histamine release evoked by antigen–antibody interactions. An increase in cAMP concentration suppresses histamine release (Lichtenstein and Margolis, 1968). Agents that activate adenylyl cyclase (e.g., catecholamines), inhibit phosphodiesterase (e.g., methylxanthines), or activate β_2-adrenergic receptors on mast cells can be anticipated to inhibit the release of histamine. The beneficial effects of drugs widely used in treating allergic disorders, such as the catecholamines, β_2-agonists, and theophylline, may therefore involve inhibition of histamine release in addition to their well-known and more important physiological antagonism of histamine actions on target cells.

Drugs and Chemicals

Many drugs and chemicals produce direct degranulation of mast cells with release of histamine independently from development of allergy (anaphylactoid reaction). This characteristic action represents an untoward side effect associated either with intravenous (IV) administration of a relatively large dose or direct intradermal injection. Certain chemicals have as their dominant property the ability to release histamine from the mast cell pool.

The curare alkaloids are used clinically as neuromuscular blocking agents (Chapter 10), but they also are notorious for releasing histamine as an adverse side effect; in some species, IV injection of these agents can be followed by histamine-induced bronchospasm and hypotension. Other clinically used drugs that may release histamine include morphine (Guedes et al., 2007), codeine, doxorubicin, vancomycin, and polypeptide antibiotics (polymyxin). However, other opiates such as oxymorphone and hydromorphone are not associated with as much histamine release (Guedes et al., 2006, 2007).

Certain chemicals have been classified simply as histamine-releasing agents because this particular activity supersedes their other pharmacological properties. The best known and most active is the polybasic substance called compound 48/80, a condensation product of *p*-methoxyphenylethylmethylamine with formaldehyde (Goth and Johnson, 1975). Injection of compound 48/80 or other similar agents evokes classic pharmacological signs of histamine release that are susceptible to blockade by antihistaminic drugs. Tachyphylaxis to repeated injections is characteristic of these chemicals, presumably because of decreased availability of releasable stores of histamine. Endogenous substances that provoke histamine release and may be involved in physiological release mechanisms include bradykinin and stronger histamine releasing substances like kallidin and substance P. Cellular reactions to many venoms (e.g., wasp venom) and toxins also involve histamine release.

Physical Injury

When the skin is scratched or pricked, the characteristic redness and urtication that result are due to histamine. This response is quite pronounced in humans. Dermal reactions to severe cold or heat stress likewise depend on histamine liberated by local mast cells. Physical injury of virtually any type sufficiently intense to damage the cells will evoke release of histamine.

Histamine Receptors

The four histamine receptors are named in the order of their discovery: histamine H_1 receptor (H_1R) to H_4 receptor (H_4R) (Table 19.1). Classic pharmacology studies led to the discovery of H_1R, H_2R, and H_3R (Akdis and Simmons, 2006). Decades later their genetic structure was decoded and they were identified as belonging to membrane-bound G-protein coupled receptors. The most recently discovered, H_4R, was described in parallel to the cloning of the DNA sequence in 2000 (Oda et al., 2000).

H_1R couples to $G_{q/11}$ and activates the PLC-IP_3-Ca^{2+} pathway. Receptor expression is found in the smooth muscles of the respiratory, gastrointestinal, and urogenital tracts. It has also been identified in neuronal tissue including brain, spinal ganglia, and spinal cord (Akdis and Simmons, 2006). Additionally, H_1R is found on immune cells like T lymphocytes, dendritic cells, and endothelial cells. Activation of H_1R causes contraction of smooth muscle, vasodilation of arterioles and capillaries, increased vessel permeability, and stimulation of

Table 19.1 Characterization of histamine receptors in terms of tissue distribution, signal transduction, and physiological and pathophysiological function. Source: Adapted from Baumer and Rossbach, 2010. Reproduced with permission of John Wiley & Sons.

Receptor	H_1R	H_2R	H_3R	H_4R
Expression tissue	Smooth muscle in respiratory, gastrointestinal, uregenital tracts and vessels, nerve cells, hepatocytes, endothelial and epithelial cells, neutrophils, eosinophils, monocytes, dendritic cells, T and B cells	Parietal cells in gastric mucosa, nerve cells, smooth muscle in respiratory tract and vessels, hepatocytes, endothelial and epithelial cells, neutrophils, eosinophils, monocytes, dendritic cells, T and B cells	Histaminergic neurons, eosinophils, monocytes	Mast cells, basophils, eosinophils, monocytes, dendritic cell, T cells, sensory nerve cells, fibroblasts and keratinocytes, endocrine cells in gastrointestinal tract
Intracellulular signal cascade	Ca^{2+}↑, phospholipase C, NFκB	cAMP ↑, adenylate cyclase, c-Fos, c-Jun, PKC	cAMP ↓, Ca^{2+} ↑, MAP kinase	cAMP↓, Ca^{2+} ↑, AP-1↑

afferent nerve endings. The effects, reddening of the skin, edema, and pruritus, are the classic symptoms of an allergic reaction. In addition to these peripheral effects, H_1R plays a pivotal role in the regulation of neuronal processes like food ingestion, the sleep–wake cycle, and triggering vomiting.

H_2R, comparably to H_1R, is widely distributed in peripheral tissues as well as in the central nervous system. The receptor is linked to G_s leading to activation of the adenylyl cyclase. One of the first actions discovered was the gastric acid production from parietal cells, which is largely mediated by H_2R (Black et al., 1972). However, beyond this effect, histamine acts via H_2R to relax smooth muscle, as has been shown in the respiratory tract, uterus, and vascular muscle. Stimulation of H_2R in the heart causes positive chronotropic and inotropic effects. Immunomodulatory action of histamine is also mediated via H_2R. Activation of H_2R influences the production of diverse cytokines in various types of cells such as monocytes, dendritic cells, and T cells, mainly to an antiinflammatory stage (Baumer and Rossbach, 2010).

H_3R couples to $G_{i/o}$ to inhibit adenylyl cyclase leading to decreased cyclic AMP. H_3R is pivotally expressed in the central nervous system (Lovenberg et al., 1999), where it is predominantly found in areas of the brain that are responsible for cognitive abilities. On the one hand, H_3R acts as an autoreceptor, regulating the synthesis and release of histamine from histaminergic neurons. On the other hand, this histamine receptor also regulates the release of various other neurotransmitters such as dopamine, serotonin, and acetylcholine from nonhistaminergic neurons (Sander et al., 2008). The wide distribution of H_3R in the central nervous system indicates a large list of possible indications for H_3R antagonists, including cognitive disorders, sleep disorders, obesity, Alzheimer's disease, and schizophrenia (Sander et al., 2008). The role of H_3R in inflammatory processes and in pruritus is also under investigation; an intradermal injection of a selective H_3R antagonist in mice can induce pruritus (Rossbach et al., 2011).

H_4R has the highest sequence homology to the H_3R. The H_4R is expressed on several cells of the immune system. Comparable to H_3R, it is coupled to $G_{i/o,}$ reducing, for example, forskolin-induced cAMP in cells. But activation of H_4R also induced Ca^{2+} influx in immune cells and sensory neurons. H_4R-expression occurs on numerous hematopoietic cells such as mast cells, basophils, eosinophils, different T cells, monocytes, macrophages, and dendritic cells (Thurmond et al., 2008). Expression of H_4R has also been shown on nerve cells of the dorsal root ganglia and in the spinal cord (Strakhova et al., 2009; Rossbach et al., 2011). H_4R seems to have a central function in modulating the immune response. H_4R influences cell activation, cell migration, and cytokine and chemokine production of various immune cells (Hofstra et al., 2003; Zampeli and Tiligada, 2009; Baumer and Rossbach, 2010). These findings have been corroborated by in vivo studies in which blockade of H_4R led to reduction of inflammation and pruritus (Thurmond et al., 2004, 2008; Cowden et al., 2010) and clinical trials with H_4R antagonists in humans for allergic-inflammatory diseases are currently under way (Kollmeier et al., 2014).

Pharmacological Effects

Histamine administered orally has essentially no effect because it is destroyed rapidly by the GI tract and liver. Intravenous histamine produces a spectrum of characteristic effects including smooth muscle contraction, hypotension, increased gastric secretion, and dermal reactions.

Difficulties are encountered when attempts are made to designate H_1- or H_2-receptor responsibility for each action of histamine. In some tissues, H_1 and H_2 receptors are complementary and subserve similar tissue responses. In contrast, distinct and even opposing functions of the two receptor types have been identified in some tissues. Species differences are formidable and in most cases await further study for classification. In the following paragraphs, only the more representative examples of H_1- or H_2-receptor involvement, when known, are discussed.

Cardiovascular System

The principal circulatory effects of histamine are dilation of terminal arterioles and other vessels of the microcirculation, edema formation caused by increased capillary permeability, and contraction of large arteries and veins. Relative dominance of the actions varies in different species so that net circulatory response to histamine changes as the zoological scale is ascended; for example, arterioles are contracted strongly by histamine in rodents, less so in cats, and actually are dilated in dogs, nonhuman primates, and humans.

In rabbits, histamine is a pressor agent as a result of pronounced constriction of large blood vessels. This constrictor activity is feeble in carnivores where vasodilation of the microcirculation dominates instead. Thus the blood pressure response to histamine in cats, dogs, and primates is hypotension caused by a sharp fall in peripheral vascular resistance. The fall in blood pressure is dose dependent but is usually short lived because of compensatory reflexes and inactivation of histamine.

The striking effects of histamine on the microcirculation can be demonstrated quite convincingly in the human subject. When this agent is administered intradermally, a characteristic triple response is produced, which includes: localized redness at the injection site, developing within a few seconds and attaining maximal hue within a minute; localized edema fluid, forming a wheal in about 90 seconds; and diffuse redness or "flare," extending about 1 cm from the original red spot. The central redness and edema are from the dilation and increased permeability of local microcirculatory vessels (terminal arterioles, capillaries, and venules). The surrounding flush, which is accompanied by itching and perhaps pain, is due to dilation of neighboring arterioles brought about by a poorly understood axonal reflex mechanism. The triple response of human skin may be similar to manifestations of urticaria in animals. Intradermal injection of histamine leads to a consistent wheal and flare reaction also in dogs. As therapeutically relevant concentrations of cetirizine reduce wheal and erythema by more than 80%, it is likely that these reactions are mainly mediated by activation of H_1 receptor (Bizikova et al., 2008).

Cardiac effects of histamine are minimal when compared to vascular actions. In the intact animal, slight tachycardia is a common finding. This response is mainly secondary to baroreceptor reflexes activated by the depressor effect. In isolated heart muscle, histamine can elicit positive inotropic and chronotropic effects that are produced partly by release of norepinephrine from nerve endings and also to direct activation of H_2 receptors in the heart muscle. There is some evidence that in vivo cardiac responses to histamine injection may partially reflect activation of cardiac H_2 receptors.

Nonvascular Smooth Muscle

Histamine contracts bronchial smooth muscle via H_1 receptors in numerous mammals including the guinea pig, cat, rabbit, dog, goat, calf, pig, horse, and human (Chand and Eyre, 1975; Mohammed et al., 1993; Vietmeier et al., 2007). Guinea pigs are exceptionally sensitive, and even minute doses of histamine can evoke bronchoconstriction leading to death. Humans with bronchial asthma likewise demonstrate increased sensitivity to bronchial effects of histamine and other bronchial smooth muscle stimulants. In contrast, histamine can mediate relaxation of respiratory smooth muscle in some species. Histamine-induced tracheal relaxation in cats involves both H_1 and H_2 receptors, while bronchial relaxation in sheep seems to be mediated by H_2 receptors (Hirschowitz, 1979).

Relaxation of the rat uterus by histamine is mediated by H_2 receptors, but uterine muscle of other species is generally contracted by histamine. Responses of intestinal muscle also vary with species and region, but the classic effect is a contractile response caused by H_1 receptors.

Peripheral Nerve Endings

In humans, nonhuman primates, and mice, intradermal injection of histamine induces itch by stimulation C-type nerve fibers (Johanek et al., 2007). Interestingly, dogs show low and very inconsistent itch behavior after intradermal injection of histamine (Carr et al., 2009). In mice and humans it has been shown that both H_1 and H_4 receptor antagonists reduce histamine induced itch, indicating also a central role for H_4R in histamine-dependent pruritus (Kollmeier et al., 2014).

Exocrine Glands

The following exocrine glands are listed in descending order of response to histamine: gastric, salivary, pancreatic, bronchial, and lacrimal. Gastric secretion of hydrochloric acid and, to a lesser degree, pepsinogen is unquestionably the most important; this response is mediated by H_2 receptors.

Medical Use

There is no direct medical use of histamine. It is used as a diagnostic agent to assess bronchial hypersensitivity in humans patients and it is serves as a positive control in humans and dogs during allergy skin testing.

Antihistamines

Although the pharmacological effects of histamine can be antagonized by several types of drugs, the term *antihistamine* is restricted to agents that act on histamine receptors.

Agents such as catecholamines and xanthines exhibit pharmacological activities that are, among other things, antagonistic to actions of histamine. However, these opposing actions are mediated by different receptors and cellular pathways; they represent physiological antagonism.

Development

Bovet and Staub (1937), of the Pasteur Institute in Paris, first demonstrated that two phenolic esters possessed antihistaminic activity. One of these compounds, 929F (thymoxyethyldiethylamine), protected guinea pigs against several lethal doses of histamine. Although the original drugs were too toxic for therapeutic use, their discovery led to development of many modern antihistamines. Such compounds are now referred to as H_1 and H_2 antihistamines, based on the previously described differentiation of histamine receptors into H_1 and H_2 subtypes (Ash and Schild, 1966; Black et al., 1972). Currently, there are also H_3 and H_4 antihistamines in clinical trials but no substance is close to marketing and only very few data exist for species relevant to veterinary science.

H_1 Receptor Antagonists

H_1 receptor antagonists are classified as inverse agonists, rather than histamine antagonists (Simons, 2004), as they reduce constitutive activity of the receptor and compete with histamine. The binding of the natural ligand histamine induces a fully active conformation, whereas antihistamine binding yields an inactive conformation. However, the term *histamine antagonists* is still often used in veterinary literature.

The H_1 antagonists have been divided into the first-generation antihistamines (e.g., chlorpheniramine, diphenhydramine, and hydroxyzine) and the second-generation antihistamines (e.g., cetirizine, loratadine, desloratadine, and fexofenadine). The second-generation antihistamines are the newer, nonsedating antihistamines. This group includes most of the newer antihistamines introduced since 1981. Some of these drugs are related: cetirizine is a metabolite of hydroxyzine and desloratadine is a metabolite of loratadine.

The primary difference between the first- and second-generation antihistamines is that the second-generation antihistamines lack the antimuscarinic properties and do not cross the blood–brain barrier as easily as first-generation antihistamines. Therefore these drugs lack the central nervous system side effects, particularly sedation, that is common with the first-generation antihistamines. The effects of each group of antihistamines will be discussed in more detail below.

Chemistry

Some of the more frequently used H_1 antihistamines are listed in Table 19.2. The chemical structure of nearly all the H_1 antihistaminic drugs can be depicted by the structural formula shown in Figure 19.2. Like histamine, many H_1 antagonists contain a substituted ethylamine (CH_2CH_2N) moiety. This moiety is thought to be the molecular component necessary for competition with histamine for specific cell receptors.

Three types of H_1 antihistamines are known, in which the element X (as depicted in Figure 19.2) is nitrogen, oxygen, or carbon. The X represents a nitrogen for the ethylenediamine class (e.g., pyrilamine, Neoantergan®), oxygen for the ethanolamine class (e.g., diphenhydramine, Benadryl®), and carbon for the alkylamine class (e.g., chlorpheniramine, Teldrin®). The fourth class of antihistamines contains a piperazine in place of the conventional ethylenediamine linkage (e.g., cyclizine, Marezine®). The representative of the fifth class (e.g., promethazine, Phenergan®) is not related directly to the

Table 19.2 Preparations and doses of some H_1 antihistamines in veterinary use

Drug class	Drug name	Brand name	Dose in animals
First-generation antihistamines (H_1 antagonists)			
Alkylamine	Chlorpheniramine	Chlor-Trimeton	Dog: 4–8 mg/dog to a maximum of 0.5 mg/kg q 8–12 h Cat: 2–4 mg/cat, q 12 h
Ethanolamine	Diphenhydramine	Benadryl	2–4 mg/kg q 8–12 h
Ethanolamine	Clemastine	Tavist and generic	0.05–0.1 mg/kg q 12 h – poor oral absorption (dogs/horses)
Piperazine	Hydroxyzine	Atarax	0.5–2 mg/kg q 8 h
Phenothiazine	Trimeprazine	Temaril, Panectyl	0.5 mg/kg q 12 h
Second-generation antihistamines (H_1 antagonists)			
	Fexofenadine	Allegra	Not established
	Loratadine	Claratin (nonprescription OTC)	Not established
	Cetirizine	Zyrtec	Horse: 0.4 mg/kg q 12 h Dog: 2 mg/kg q 12 h Cat: 1 mg/kg daily
	Desloratadine	Clarinex	Not established

previous drugs; it is a phenothiazine derivative. The sixth class comprises the piperidines terfenadine and fexofenadine; these agents have aromatic ring moieties on either end of the ethylamine chain. Terfenadine is no longer used due to cardiotoxicity (QT interval prolongation); fexofenadine lacks this side effect. These different chemical substitutions influence the potency of H_1-antihistaminic action as well as their side effects.

Pharmacological Effects

Pharmacokinetic information for the antihistaminics of the H_1 subtype in different species is sparse. Chlorpheniramine is well absorbed in dogs, with a short time to peak absorption after oral administration and a half-life of 24 hours. Some are absorbed poorly (clemastine) (Hansson et al., 2004), while others appear to be well absorbed, but rapidly converted to a metabolite (hydroxyzine) (Bizikova et al., 2008). There are little data available for horses or ruminants. When clemastine was administered to horses (Törneke et al., 2003), there was a rapid decline in plasma concentrations. Oral absorption was only 3% at a dose of 0.2 mg/kg. There has been some PK/PD modeling in horses with oral administration of cetirizine. A dose of 0.4 mg/kg cetirizine BID resulted in nearly 70% wheal inhibition induced by histamine; the half-life of cetirizine was roughly 6 hours in this setting (Olsén et al., 2008).

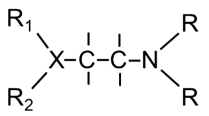

Figure 19.2 General formula of most H_1 antihistaminic agents.

In species for which oral absorption occurs, effects are usually expected within 20–45 minutes, and the duration of action ranges from 3 to 12 hours (Table 19.2). IV administration elicits immediate effects, but this route is not used except for treatment of acute anaphylaxis (for which epinephrine is the preferred treatment of choice). Rapid IV injection can produce stimulation of the CNS and other side effects. The intramuscular route rarely gives rise to side effects and is more commonly used than IV administration. Topical application may be suitable in certain skin conditions, but antihistamines can be skin sensitizing, particularly during long-term use (Robinson and Cruze, 1996).

Antihistamines act as inverse agonists to stabilize a low constitutive activity of the histamine H_1 receptors in the tissue cells; their binding to the cell receptors evokes no direct cellular action. This mechanism of action is based on quantitative considerations; therefore, histamine in excess may displace antihistaminics. Generally, antihistaminics are more effective against exogenously administered histamine than against endogenously released histamine. They are also more effective in preventing actions of histamine than in reversing them (Simons, 2003).

Therapeutic Uses

Generally, H_1 antihistaminics are useful in countering action of histamine on bronchial, intestinal, uterine, and vascular smooth muscle (Gelfand et al., 2004). They antagonize both the vasoconstrictor effects of histamine and the more important vasodilator effects, as well as the increase in capillary permeability produced by this agent. These antihistaminic effects counteract urticaria, wheal formation, and other types of edema formation in response to injury, antigens, allergens, or histamine-liberating drugs. H_1 antihistaminics also suppress itching and flare in humans and greatly reduce itching associated with allergic reaction. In addition to the traditional effect on histamine response, these drugs may have other antiinflammatory/immunomodulatory effects, including decrease of the release of inflammatory mediators from inflammatory cells such as mast cells (Simons and Simons, 1994; Walsh, 2005). The relevance of this activity to clinical response is not known, nor is it known if this occurs at clinically achieved plasma concentrations. H_1 antihistaminics only partially antagonize histamine-induced arterial hypotension because portions of this response are associated with H_2 receptors. The H_1 antagonists do not block the stimulant effect of histamine on gastric secretion, which is an H_2-dependent function. Importantly, neither H_1 nor H_2 antihistamines prevent histamine release; some antihistaminics rather seem to possess histamine-liberating properties.

Veterinary Medicine

H_1 antihistaminics are frequently used in animals and representative doses are given in Table 19.2; however, as mentioned above, there are only few PK/PD data available for H_1 antagonists and most data are extrapolated from use in human medicine. Clinically, H_1 antagonists are used to prevent reactions from endogenous histamine as a response to certain allergic disorders and anaphylactic syndromes. However, the clinician must be aware that autacoids other than histamine also play important roles in allergy-anaphylaxis disorders. During mast cell degranulation, apart from histamine, the following mediators are released and secreted: serotonin, dopamine, kinins, prostaglandins, leukotrienes, platelet activating factor, complement, and several cytokines and chemokines. Thus it is not surprising that antihistamines alone are often ineffective in treating allergic-type reactions in animals.

Clinical signs of allergy vary among different species. The most frequently observed signs are restlessness, anorexia, yawning, salivation, lacrimation, nasal discharge, coughing, edema, urticaria, pruritus, eczema, necrosis, hemorrhage, inflammation of the mucous membranes and eyes, contraction of smooth muscle (bronchoconstriction), and cardiovascular disturbances. In acute or delayed anaphylaxis, clinical signs occur quickly and, if not treated, are followed by collapse and death in minutes.

Treatment of allergic conditions (e.g., atopic dermatitis) consists of further avoidance of allergens, hyposensitization, corticosteroids, cyclosporine, oclacitinib, and, rather as add on therapy, the administration of H_1 antihistaminics.

Treatment of Pruritus

The most extensively studied clinical problem in veterinary medicine for which antihistamines have been used is pruritus associated with atopic dermatitis (Papich, 2000; DeBoer and Griffin, 2001). Evidence-based reviews were published by Olivry et al. (2003, 2010, 2013). In some reports the incidence of response is approximately the same as a placebo. Several of the reported studies are uncontrolled, or the studies are not published in reviewed references. Nevertheless, these drugs are used by dermatologists to decrease the reliance on corticosteroids or used in conjunction with other antiinflammatory medications. As reported by Zur and colleagues (2002), dermatologists will often try three to five antihistamines in 2-week trials to find the one that is most effective for a patient. As expected, because of these individual variations, there also are a variety of results reported. Zur and colleagues (2002) evaluated hydroxyzine, diphenhydramine, chlorpheniramine, and clemastine in a retrospective study. Overall, 54% of the dogs had a good to moderate response. In that study, diphenhydramine and hydroxyzine were the most often used, and the most often effective. The second-generation antihistamine fexofenadine was tested in a small clinical trial (15 dogs) in the comparably high dose of 18 mg/kg over 6 weeks. At the end of the study, 80% of the dogs showed a reduction in pruritus >50% (Olivry and Bizikova, 2013). Although encouraging, larger studies are needed to test the efficacy and safety of fexofenadine for the treatment of atopic itch.

Clemastine (Tavist), an ethanolamine antihistamine, has a poor oral availability in dogs (Hansson et al., 2004) and horses (3%) and it is thus not recommended to be administered orally. Chlorpheniramine, diphenhydramine, and hydroxyzine may be effective in some dogs (Scott and Buerger, 1988). Trimeprazine, a phenothiazine derivative with antihistamine effects, has little effect on its own, but is among the most effective drugs when combined with a corticosteroid (prednisolone).

Cetirizine, one of the second-generation drugs, is an active metabolite of hydroxyzine. Some veterinarians have claimed some success, but it was modest at 1 mg/kg/day (18% response). In a study in dogs (Bizikova et al., 2008), it was shown that hydroxyzine (a first-generation antihistamine) was rapidly converted to cetirizine (a second-generation antihistamine) in dogs. This conversion was rapid regardless of the route (IV or oral at a dose of approximately 2 mg/kg). Moreover, the observed reaction to histamine was attributed to the plasma concentrations of cetirizine, not hydroxyzine. Therefore, hydroxyzine – one of the most popular antihistamines used in dogs – appears to act as a prodrug. A controlled blinded cross over study comparing dimetinden (0.1 mg/kg) with the combination of 0.07 mg/kg chlorpheniramine and 2 mg/kg hydroxyzine in dogs suffering from atopic dermatitis confirm the overall moderate effect of H_1 antihistamines on pruritus as well as on skin lesions (Eichenseer et al., 2013). These results are corroborated by findings in a dog model of atopic dermatitis; the determination of histamine after allergen challenge in atopic dogs sensitized to house dust mite antigen revealed that only within the first 30 to 45 minutes, there was a transient increase of histamine in the skin. Both, histamine H_1 and H_4 receptor antagonists did not prevent the generation of acute skin lesions in this dog model (Baumer et al., 2011). An effect on itch, however, was not determined in this study and awaits further investigation.

Chlorpheniramine and clemastine also have been reported to reduce pruritus in cats (Miller and Scott, 1990). The effects or pharmacokinetics of antihistamines in this species have not been studied as much as in dogs. In one study, cetirizine (ca. 1 mg/kg) was well absorbed in cats and produced plasma concentrations that were above the levels considered therapeutic in humans.

Some studies have shown that combinations of antihistamines with fatty acids or other drugs may improve efficacy. There may be a synergistic effect of antihistamines (e.g., clemastine, chlorpheniramine) in combination with n-3/n-6 fatty acids (Paradis et al., 1991a), and evidence for a synergistic effect with fatty acids and corticosteroids. When antihistamines were combined with corticosteroids in one report, the effective dose of prednisone was lowered (30% reduction) (Paradis et al., 1991b). In a study in dogs, a combination of a fatty acid product plus clemastine was more effective (43% response) than either drug used alone (Paradis et al., 1991a). In cats, chlorpheniramine plus fatty acids were more effective than either drug used alone. Despite these positive results, the study by Zur et al. (2002) did not show combinations to be helpful.

There are only few data on antihistamine treatment of horses suffering from insect bite hypersensitivity (“sweet itch”). Cetirizine at the dose of 0.4 mg/kg BID did not show any effect on dermatitis score (Olsén et al., 2011).

Treatment of Anaphylaxis

Anaphylactic syndrome requires emergency treatment because it progresses rapidly to irreversible cardiovascular collapse. The drug of choice is epinephrine; this catecholamine does not directly inhibit mediators of anaphylaxis but reverses their effects. Thus epinephrine acts as a physiological antagonist (see Chapter 7).

Treatment of Respiratory Disorders

The use of antihistamines for treatment of inflammatory airway disease and asthma has been of only minor benefit, suggesting the important contribution of other inflammatory mediators in this disease.

Cetirizine produced a protection against bronchoconstriction in humans affected with mild asthma during histamine challenge and may have other antiinflammatory properties (Walsh, 2005). However, in sensitized asthmatic cats, cetirizine at a dose that produces plasma concentrations considered effective in people (5 mg per cat every 12 h) was ineffective in attenuating the infiltration of inflammatory eosinophils in airways or in altering other immune variables (Schooley et al., 2007). These authors recommended that cetirizine (and perhaps other antihistamines) should not be considered as sole therapy for asthma in cats. Antihistamines also are considered to be of value in treatment of bovine asthma (pulmonary emphysema). Chapter 48 presents a more detailed discussion of drugs that affect the respiratory system.

Treatment of Other Conditions with Antihistamines

Nonallergic but suspected histamine-related phenomena, which in empirical experience respond to antihistaminic therapy in animals, include many pathological conditions. Those in which H_1 antihistaminics are reported to be of therapeutic value are: urticaria, various types of dermatitis, moist eczema, acute eczematous otitis, insect stings, nutritional types of laminitis, pregnancy laminitis, paroxysmal myoglobinuria or azoturia, periodic ophthalmia, and pulmonary emphysema in horses. In cattle, antihistamines also are considered to be of value in treatment of some types of bloat and acetonemia in ruminants, acute septic and gangrenous mastitis, septic metritis and retained placenta, pregnancy toxemia, and gut edema of pigs. Treatment of vestibular stimulation (motion sickness) in animals has been variable. Although these drugs are sold over-the-counter for this purpose for humans, they appear to be less effective for vestibular vomiting in animals (Yates et al., 1998).

Side Effects and Interactions

In recommended doses H_1 antihistaminics are relatively nontoxic. Side effects of clinical importance for the H_1 blockers include sedation or CNS excitement, GI disturbances, parasympatholytic action, local anesthetic properties, allergenic properties, and teratogenic effects. In therapeutic doses, the first generation H_1 antihistaminics elicit a sedative effect expressed by drowsiness or ataxia. The newer, second-generation antihistamines are more popular in people because they are considered nonsedating. Some dermatologists have acknowledged that the effect on reducing pruritus in dogs after administration of first-generation antihistamines may be partially attributed to the sedation produced (DeBoer and Griffin, 2001; Olivry et al., 2003, 2010). Despite an assumption that first-generation antihistamines cause sedation in animals, a study of diphenhydramine in dogs indicated that this assumption may be incorrect. When dogs were administered doses of 2, 4, or 8 mg/kg IM compared to acepromazine or saline, the dogs receiving acepromazine showed significant sedation but sedation in dogs receiving diphenhydramine was no different from saline (Hofmeister and Egger, 2005).

In much higher doses they produce irritability, convulsions, hyperpyrexia, and even death. Intestinal disorders include anorexia, nausea, vomiting, constipation, or diarrhea when antihistamines are administered orally for a prolonged period. The anticholinergic effects are expressed by dry mouth, pupillary dilation, blurred vision, and tachycardia. Local anesthetic properties may be of value when these agents are used as antipruritic drugs in topical application. The teratogenic effects of certain of these agents suggest caution in their use during pregnancy.

The newer, second-generation H_1 antihistamines – fexofenadine, cetirizine, loratadine – are largely excluded from the CNS when given in therapeutic doses because they are better substrates for the P-glycoprotein (P-gp) membrane pump that is an important component of the blood–brain barrier (Sun et al., 2003; Janssens and Howart, 1993; Meeves and Appajosyula, 2003). Their lack of sedation as a side effect is a distinct advantage in human medicine. Study is needed in veterinary medicine to determine their clinical efficacy and whether lack of sedation is an important attribute in animals (Miller et al., 1989).

H_2 Receptor Antagonists

H_2 antagonists block the gastric stimulating effects of histamine as well as other actions of histamine that have been defined as H_2-receptor dependent (e.g., stimulation of rat uterus, cardiac excitatory effects, and some vascular effects).

The H_2 antihistamines differ from the H_1 blockers in their chemistry, pharmacokinetics, and pharmacodynamics. The imidazole ring structure of histamine is modified extensively or replaced by other substituents in the H_1 antagonists. In the H_2-blocking agents, however, the side chain is modified extensively, while the imidazole moiety is preserved. In contrast to the H_1 antihistaminics, the H_2 antagonists are somewhat less lipid soluble and do not effectively penetrate the blood–brain barrier. Hence, the H_2 antagonists do not cause sedation, a prominent side effect of most of their H_1 counterparts.

Burimamide was the first H_2 antagonist, but it was absorbed too poorly to be effective after oral administration. Cimetidine, ranitidine, and famotidine are some of the newer H_2 blockers used extensively in prevention and treatment of gastric ulceration in humans and animals. (H_2-blocking drugs used to treat stomach disorders are discussed in more detail in Chapter 46.)

Serotonin

Rapport et al. (1948) isolated a vasoconstrictor substance from serum and gave it the name serotonin; it was subsequently identified as 5-hydroxytryptamine (5-HT). Another group of researchers studying histochemical properties of the intestinal mucosa discovered an active agent in enterochromaffin cells and gave it the name enteramine (Erspamer and Asero, 1952). After discovery of 5-HT in blood, it was soon confirmed that enteramine and 5-HT were the same chemical structure.

Following discovery of 5-HT and multiple types of 5-HT receptors in the CNS, it was soon discovered that drugs affecting 5-HT in the brain had beneficial CNS actions including modification of behavior, antidepressant actions, and antianxiety effects (Sanders-Bush and Mayer, 2006). Drugs that modulate 5-HT action are being used increasingly in veterinary medicine in attempts to control behavioral problems in animals, and modify gastrointestinal motility (for additional information see Chapters 18 and 46) (Crowell-Davis and Murray, 2006; Mohammad-Zadeh et al., 2008).

Sources, Synthesis, and Metabolism of Serotonin

5-HT is synthesized from dietary tryptophan in a two-stage chemical reaction (Walther et al., 2003). First, tryptophan is hydroxylated by the enzyme tryptophan 5-hydroxylase to give 5-hydroxytryptophan (5-HTP). The latter is then decarboxylated to yield 5-HT (serotonin), as shown in Figure 19.3.

Like histamine, 5-HT is widely distributed in animals and plants (Sanders-Bush and Mayer, 2006). It occurs in high concentration in some fruits such as bananas, pineapples, and plums; it also is present in stings (common stinging nettle) and venoms. Endogenous 5-HT is synthesized from about 1% of the dietary tryptophan. It is formed and localized in three essential pools: enterochromaffin cells of the intestine, select neurons in the CNS, and mast cells of rodents (rats, mice, hamsters), and possibly other species (conflicting results), along with histamine and heparin. Although 5-HT is concentrated in blood platelets, it is not synthesized there because of lack of decarboxylase. It appears to be bound within cytoplasmic granules and is also continually produced and destroyed in the pool of the intestine and brain. In platelets it appears to be released only upon their destruction.

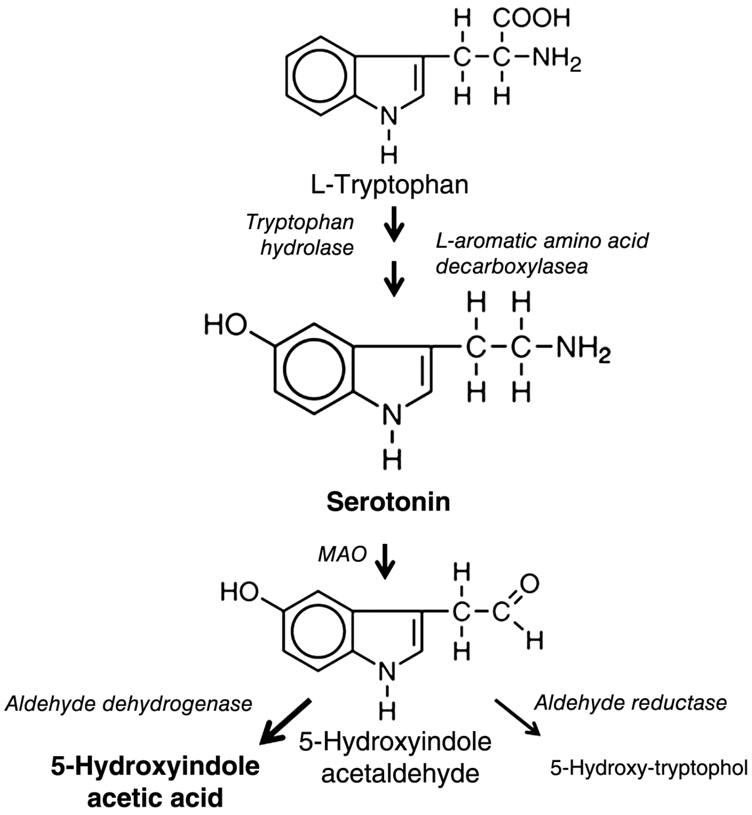

Figure 19.3 Synthesis and metabolism of serotonin. Serotonin is synthesized from L-tryptophan by a two-step pathway via 5-hydroxytryptophan. The main route of metabolism of serotonin involves oxidative deamination by monoamine oxidase (MAO). Via an aldehyde intermediate, the main metabolite is 5-hydroxyendole acetic acid. The reduction to 5-hydroxytryptophol is normally insignificant.

Most 5-HT is metabolized by oxidative deamination to form 5-hydroxyindoleacetic acid (5-HIAA); the enzyme catalyzing this reaction is monoamine oxidase (Figure 19.3). The end product of metabolism, 5-HIAA, is excreted in urine. However, in the pineal gland, *N*-acetylation and 5-methylation of 5-HT form the hormone melatonin.

Neuronal Uptake of 5-HT

After 5-HT is synthesized, it is stored within secretory granules in the axon terminal from which it is released by exocytosis upon arrival of the action potential. The action of intrasynaptic 5-HT is terminated in large part by a neuronal membrane uptake transporter localized in the axon terminals of the 5-HT neurons. This reuptake by the neurons diminishes 5-HT availability at the postsynaptic 5-HT receptors of the effector cells, thereby regulating the duration and intensity of action of 5-HT. Pharmacological blockade of the 5-HT uptake mechanism thereby prolongs the availability and action of 5-HT at its receptors on the effector cells. The action of 5-HT is subsequently intensified. The 5-HT transporter (SERT) has been cloned; it is selective for 5-HT and distinctly different from the intraneuronal storage granule uptake mechanism.

The 5-HT neuronal uptake transporter has become important to neuropharmacology in both human and veterinary medicine (Crowell-Davis and Murray, 2006). Drugs that inhibit 5-HT uptake, known as selective serotonin reuptake inhibitors (SSRIs or SRIs), are used extensively to treat depression and other neurological disorders, alone or jointly with drugs that inhibit norepinephrine reuptake into noradrenergic neurons (Sanders-Bush and Mayer, 2006). In veterinary medicine SSRIs are used in attempts to control various behavioral disorders in small animals (see Chapter 18). Their clinical use is becoming more common in animals owing to the increased recognition by veterinarians that treatment of behavioral problems in dogs and cats can often be facilitated by drugs that enhance the action of CNS neurotransmitters such as 5-HT, norepinephrine, and dopamine (Crowell-Davis and Murray, 2006). The SSRIs include citalopram (Celexa®), sertraline (Zoloft®), fluoxetine (Prozac®, Reconcile®), and paroxetine (Paxil®). Of these, only fluoxetine has been registered for dogs, although the others have been used off-label. Clomipramine (Clomicalm®, Anafranil®) is a tricyclic antidepressant that has been approved for the treatment of separation anxiety in dogs; it inhibits the neuronal reuptake of both 5-HT and, to a far lesser extent, norepinephrine (Crowell-Davis and Murray, 2006).

Subtypes of 5-HT Receptors

Because of the wide variety of pharmacological actions produced by 5-HT, multiple types of receptors seemed likely (Bonasera and Tecott, 2000). Subsequent investigations, including cloning of receptor cDNAs, confirmed that there was indeed an impressive variety of 5-HT receptor families comprising at least seven major receptor types and several respective subtypes. Although their full spectrum of physiological effects and pharmacodynamic actions has only been partially characterized, most of the 5-HT receptors (except 5-HT_3) are believed to be typical G-protein coupled receptor complexes (Sanders-Bush and Mayer, 2006).

The seven major 5-HT receptor families are designated as 5-HT_1 through 5-HT_7. The 5-HT_1 family has five members designated 5-HT_{1A}, 5-HT_{1B}, 5-HT_{1D}, 5-HT_{1E}, and 5-HT_{1F}. All five 5-HT_1 receptors inhibit adenylyl cyclase, thereby reducing intracellular concentrations of the cyclic nucleotide cAMP. The 5-HT_{1A} receptor also inhibits a voltage-gated Ca^{2+} channel, but activates a receptor-coupled K^+ channel. The 5-HT_1 receptors in the CNS subserve a variety of excitatory and inhibitory neurotransmitter actions in different regions of the brain. 5-HT_{1A}-receptor agonists include buspirone, gepirone, and ipsapirone; these agents comprise a new class of antianxiety drugs in human medicine. Some experience exists in cats with buspirone (see Chapter 18). The 5-HT_{1D} agonist sumatriptan constricts intracranial blood vessels, an action that helps reduce migraine headaches in humans. The 5-HT_{1B} selective agonists seem to share this action.

Three subtypes of 5-HT_2 receptors (5-HT_{2A-C}) also have been identified; they activate the phospholipase C-diacylglycerol-inositol triphosphate triade, culminating in mobilization of intracellular Ca^{2+} stores (Janssen, 1983; Gray and Roth, 2001).

Unlike the other 5-HT receptor types, the 5-HT_3 receptor is the only known monoamine receptor believed to serve as a ligand-operated ion channel (Derkach et al., 1989), somewhat analogous to the nicotinic cholinergic receptor. The 5-HT_3 receptor promotes a rapidly desensitizing depolarization, presumably due to the efflux of K^+ through its opened channels. The 5-HT_3 receptors are present both in the CNS and peripheral neurons, with one action associated with coordination of the emetic response.

The 5-HT_4 receptors are located in various regions of the CNS and the gastrointestinal tract (Hegde and Eglen, 1996), where they are coupled to activation of adenyl cyclase through the excitatory G-protein (G_S). The actions and effects of the 5-HT_5, 5-HT_6, and 5-HT_7 receptor types remain to be clearly defined (Sanders-Bush and Hazelwood, 2011). Data indicate a role of 5-HT_6 in cognitive functions (Ramírez, 2013); the 5-HT_7 is also involved in learning and memory but additionally plays a role in thermoregulation and influences the circadian rhythm (Gellynck et al., 2013).

Pharmacological Effects

5-HT exerts multiple actions with great variation in different species, reflecting its multiple locations and plethora of receptor types. Its essential effects are on smooth muscle and central and peripheral nerves, including afferent nerve endings. Given orally, it is quickly degraded and produces no effect.

Rapid IV injection of 5-HT produces a triphasic response: an initial fall of systemic arterial pressure accompanied by paradoxical bradycardia, caused mainly by activation of 5-HT_3 receptors on vagus nerve endings (Bezold-Jarisch effect); a short period of pressor effect (similar to epinephrine effect); and a prolonged fall in systemic blood pressure attributed to a vasodilator effect in the vascular bed of skeletal muscle. 5-HT also causes a fall in pulmonary arterial pressure (pulmonary depressor reflex). A continuous infusion of 5-HT, which most closely resembles endogenous release of this agent, causes a prolonged fall in arterial pressure as a result of vascular bed dilation. Only in rodents does this agent increase small vessel permeability similar to effects of histamine.

The nonvascular smooth muscle of the bronchi and intestines is stimulated by 5-HT. In the intestine, as a local hormone, 5-HT initiates a peristaltic reflex in response to local stimulation. Among the receptors, 5-HT_3 is inhibitory, and 5-HT_4 is excitatory. Several drugs affect these receptors: cisapride is an agonist for 5-HT_4; metoclopramide is an agonist for 5-HT_4 and (weak) antagonist for 5-HT_3. Ondansetron, which is used as an antiemetic agent has modest prokinetic activity via 5-HT_3 antagonism. Tegaserod and prucalopride, two newer drugs for which only experimental data exist for animals, act as 5-HT_4 agonists with colon-specific effects. The clinical use of these drugs to affect GI motility is discussed in more detail in Chapter 46.

When 5-HT is injected, it has no effect on the brain or spinal cord because it is strongly polar and cannot effectively cross the blood–brain barrier. However, 5-hydroxytryptophan (5-HTP) can penetrate into the brain and be decarboxylated to 5-HT; this may produce behavioral changes. 5-HT can also stimulate afferent nerve endings, ganglion cells, and adrenal medullary cells. 5-HT can also stimulate vomiting because the chemoreceptor trigger zone that stimulates vomiting in the area postrema is outside of the blood–brain barrier.

Role in Physiological and Pathological Processes

The finding that 5-HT is present in the CNS, the hypothalamus, and other areas led to identification of its role as a central neurotransmitter. 5-HT influences sleep, sensory perception, cognition, motor activity, appetite, intestinal motility, temperature regulation, and mood and behavior (Crowell-Davis and Murray, 2006). An excess of this agent brings about CNS stimulation and mood elevation, while a deficiency produces mood depression. The addition of SSRIs as a separate class of antidepressant drugs followed the realization that increasing the concentration of 5-HT at its CNS receptor sites could improve mood (see Chapter 18). In the peripheral nervous system, 5-HT is involved in the perception of itch and pain (Liu and Ji, 2013). The role of 5-HT in platelets is related to the mechanism of hemostasis via both vasoconstriction and platelet aggregation.

5-HT Agonists and Antagonists

Because several classes and subclasses of 5-HT receptors have been identified (Derkach et al., 1989), it is not surprising that 5-HT receptor antagonists and agonists comprise a broad group of chemically unrelated compounds. Neural effects of 5-HT in smooth muscle of the digestive tract are antagonized by morphine, atropine, and cocaine; the direct effects on smooth muscle are antagonized by phenoxybenzamine. Chlorpromazine and phenoxybenzamine are weak 5-HT receptor blocking agents. Reserpine depletes serotonin (and other monoamines) in the synapses by inhibition of the vesicular monoamine transporter. Cyproheptadine acts on 5-HT_{1A} receptors, but it is also a H_1 antihistamine. Ketanserin is a 5-HT antagonist that acts preferentially at the 5-HT_{2A} receptor subtype without significant action at the 5-HT_1 or 5-HT_3 receptors. It is also a weak H_1 antihistamine and α-adrenergic blocker.

The areas in which drugs have been most widely investigated in veterinary medicine are the use of cyproheptadine in animals to treat inflammatory conditions and to stimulate appetite, the use of serotonin antagonists to treat vomiting, the use of serotonin agonists to stimulate gastrointestinal motility, and the use of drugs that modify serotonin CNS receptors or alter the reuptake of serotonin to treat behavioral disorders. The use for treating behavior disorders is discussed in detail in Chapter 18 and by Crowell-Davis and Murray (2006). The gastrointestinal uses of these drugs (agonists and antagonists) are discussed in Chapter 46.

Cyproheptadine

Cyproheptadine (Periactin®) is a serotonin antagonist and a modest antagonist for histamine (H_1). It has been used to treat inflammatory conditions of the skin (dermatitis) and the airways. It is also used as an appetite stimulant in cats, presumably by inhibiting serotonergic receptors in the hypothalamus that control satiety. Doses used to stimulate appetite in cats are in the range of 1 mg per cat orally once daily, to as high as 8 mg orally, every 8 hours. In cats the half-life is approximately 8 and 12 hours after IV and oral administration, respectively, suggesting that twice-daily administration would be sufficient in most cats (Norris et al., 1998). It was completely absorbed after oral administration (Norris et al., 1998).

Serotonin is reported to be one of the inflammatory mediators in the airways of animals – particularly the acute phase response of asthma. Therefore, serotonin antagonists such as cyproheptadine in cats should theoretically produce some benefit against smooth muscle constriction, vasodilation, increased vascular permeability, and inflammatory cell influx. Cyproheptadine attenuated the smooth muscle constriction induced by serotonin in airway smooth muscle from sensitized cats (Padrid et al., 1995). Cyproheptadine also has decreased airway reactivity to serotonin infusion in healthy cats (Reiche and Frey, 1983) and at a dose of 2 mg/kg orally q 12 h it decreased airway reactivity in cats with airway hyperresponsiveness (Reinero et al., 2005). However, in cats with experimentally induced asthma, cyproheptadine at a dose of 8 mg per cat orally produced limited results (Schooley et al., 2007). It did not decrease eosinophilic infiltration in the airways of treated cats. These authors suggested that perhaps mediators other than histamine and serotonin are responsible for airway responses in asthmatic cats and antihistamines and cetirizine as sole therapy will produce minimal benefit. Adverse effects in cats have not been studied, but side effects of aggression and stimulation have been observed. Additional discussion of drugs that affect the respiratory tract is included in Chapter 48.

Side Effects and Interactions

Side effects of 5-HT agonists and antagonists vary, mainly due to their specific receptor interaction or due to the site of action. Generally, care must be taken to avoid the “serotonin syndrome” (or serotonin toxicity), characterized by an excess of serotonin in the CNS. Clinical signs include nausea, vomiting, mydriasis, hypersalivation, and hyperthermia (Fitzgerald and Bronstein, 2013). Thus, combinations of SSRI, monoamine oxidase inhibitors, and tricyclic antidepressants should be avoided. For details of specific side effects of 5-HT agonists and antagonist please refer also to Chapters 18 and 46.

Analgesic, Antiinflammatory, Antipyretic Drugs

Peter Lees

Scientific Literature

The published literature on nonsteroidal antiinflammatory drugs (NSAIDs) is voluminous in quantity but not always matched by quality; in amount, it is greater than any individual can read in a lifetime. For those wishing to rise to this challenge, the following chapters and reviews are recommended as a starting point: Vane, 1971; Warner et al., 1999; Flecknell and Waterman-Pearson, 2000; Lees et al., 2004a,b, 2015; Bergh and Budsberg, 2005; Robertson, 2005; Lascelles et al., 2005, 2007; Papich, 2007, 2008; Budsberg, 2009; Innes et al., 2010; Kukanich et al., 2012; Lees and Toutain, 2013). The reader is also referred to the USP monographs on individual drugs (Veterinary Medicine Expert Committee on Drug Information, 2004).

The Role of Eicosanoids in Inflammation and Mechanisms of Action of NSAIDs

Acute inflammation is characterized by the four cardinal signs of heat, redness, swelling, and pain, as first described by the Roman physician Celsus in the first century AD, to which Virchow added the fifth sign, loss of function, in the 19th century. Three of the cardinal signs involve the microcirculation, being caused by arteriolar dilatation and increased permeability of capillaries and postcapillary venules to protein, leading to formation of an inflammatory exudate rich in leukocytes. The infiltrate is first dominated by polymorphonuclear leukocytes and later by mononuclear cells, which transform to macrophages in the interstitial space. Leukocytes are the scavengers of the inflammatory process, engulfing microorganisms, particulate matter, and dead and dying cells, and releasing enzymes and chemicals, the mediators of inflammation. Inflammatory processes are driven by a wide range of mediators, synthesized de novo or released from cell storage sites, in a timed manner in both the early and resolution phases of acute inflammation and in chronic inflammation. Many mediators interact with other mediators by addition, antagonism, or synergism.

Arachidonic acid (AA), a 20-carbon ω-6 unsaturated fatty acid, plays a pivotal role in inflammation as the precursor of the eicosanoid group of mediators. AA is an esterified component of cell membrane phospholipid, released in tissue damage following the action of endogenous peptides, the lipocortins, which activate phospholipase A_2. There are several isoforms of phospholipase A_2 and it is the cytosolic 85-kDa isoform that normally supplies AA. AA serves as a substrate not only for prostaglandin (PG)H synthase, more commonly known as *cyclooxygenase (COX),* of which there are two isoforms COX-1 and COX-2, but also several lipoxygenases (LO), including 5-LO, 12-LO, and 15-LO. Each enzyme is a component of a cascade, in which the action of further enzymes leads to the formation of eicosanoids. They are described as autacoids, as they act locally at the site of synthesis. Moreover, they are short lived, so that continued effect depends on maintained synthesis and release. COX catalyses both the formation of PGG_2 and then PGG_2 conversion to PGH_2 via a peroxidase function.

At an early stage of acute inflammation, several PGs (including PGE_2, PGI_2, and PGD_2) are synthesized from AA, the product profile being determined by differing downstream enzymes. For example, cytosolic PGE synthase is mainly coupled with COX-1, whilst an inducible microsomal or membrane-associated perinuclear PGE synthase, regulated by cytokines and glucocorticoids, is coupled with COX-2 (Murakami et al., 1999).

PGs are cyclic five-carbon structures; the two COX isoforms generating PGs consist of a long narrow channel with a hairpin bend at the end. For COX-2 the substitution of valine for isoleucine creates a wider channel than for COX-1. Selective COX-2 inhibitors have a broader conformation, so that they enter the COX-1

channel less readily. A further difference is the kinetics of binding of NSAIDs to each isoform. COX-1 inhibition involves hydrogen bonding, is instantaneous and competitively reversible, except for aspirin. COX-2 inhibition may involve covalent binding, is time dependent, and slowly reversible.

Eicosanoid receptors are cell membrane spanning and G-protein coupled; several subdivisions have been classified, corresponding to each COX metabolite, for example DP for PGD_2, EP for PGE_2, FP for $PGF_{2\alpha}$, and IP for PGI_2. The actions of PGE_2 are mediated by a range of receptor subtypes (EP1, EP2, EP3, and EP4) activation of which leads to ongoing intracellular signaling pathways. The EP4 receptor is associated with inflammatory pain and has been implicated in rheumatoid and osteoarthritis (OA). Grapiprant, a selective EP4 receptor antagonist, is under development for use in dogs with OA (Rausch-Derra and Rhodes, 2015).

Following synthesis, PGs must exit the cell; ABC genes provide ABC transporters to consume ATP, facilitating transfer across cell membranes. For example, MRP4 has particular affinity for transporting PGE_2, TxA_2, and $PGF_{2\alpha}$ (Warner and Mitchell, 2003).

Several examples of synergism between proinflammatory PGs and other inflammatory mediators may be cited. First, both histamine (Chapter 19) and bradykinin are primary inflammatory mediators, which stimulate nociceptors (peripheral nerve endings) to increase the discharge in afferent nerves, so that pain is sensed in spinal and brain centers. PGE_2 synergizes with these primary mediators to increase both intensity and duration of the afferent discharge, a phenomenon termed *hyperalgesia* (Ferreira, 1983). In addition, when tissues are damaged, stimuli (e.g., touch) that are not normally painful, become painful, a phenomenon termed *allodynia*; PGs are again implicated (Nolan, 2001). It is by inhibiting PG synthesis that NSAIDs exert their analgesic actions.

Second, histamine and bradykinin increase endothelial intercellular gaps in capillary and small postcapillary venules, to increase loss of plasma into the interstitial space. This alteration to the Starling balance of forces causes exudation of plasma, accounting for one of the classical signs of acute inflammation, edema. PGs do not alter capillary permeability directly but, by dilating small arterioles, they enhance the edema induced by the primary mediators. Inhibition of synthesis of PGs by NSAIDs explains their antiedematous actions.

Third, there is synergy between proinflammatory mediators in the induction of COX-2 protein and in the supply of AA to enhance prostanoid production at inflammatory sites. Hamilton et al. (1999) showed that lipopolysaccharide (LPS)-induced COX-2 induction alone did not greatly increase prostanoid production, but it was markedly increased by bradykinin administration through an increase in the supply of the substrate AA.

COX-2 generates *antiinflammatory* as well as *proinflammatory* PGs; COX-2 is up-regulated not only in the early stage (2 hours) of acute inflammation but also in the resolution phase (around 48 hours). The early peak of COX-2 production is associated with the synthesis of proinflammatory PGE_2 by polymorphonuclear leukocytes, while the later peak is associated with the synthesis of antiinflammatory PGs (Gilroy et al., 1998, 1999). These include 15deoxy$\Delta^{12-14}PGJ_2$ ($15dPGJ_2$) synthesized by mononuclear cells; $15dPGJ_2$ is a ligand for the nuclear receptor peroxisome proliferator-activated receptor-γ (PPAR-γ) and some of its actions may result from activation of PPAR-γ (Kawahito et al., 2000). Inhibition of synthesis of $15dPGJ_2$ with COX-2 selective as well as with nonselective NSAIDs theoretically might lead to a more protracted resolution/ healing phase in acute inflammation (Konturek et al., 2005) although this has not been identified as a clinical problem.

As well as the peripheral/ local roles of PGs, they are involved in pain perception at the spinal level. Spinal nociceptive processing is facilitated by firing of neurons and enhancement of transmitter release from primary spinal sensory afferents. Furthermore, PGE_2 is also an endogenous pyrogen, leading to upward resetting of the temperature regulating center in the anterior hypothalamus.

Proinflammatory PGs and leukotrienes (LTs) are synthesized from AA by the catalytic actions of COX and 5-LO, respectively. ω-3 fatty acids, present in high concentrations in fish oils, include eicosapentanoic acid (EPA) and docosahexanoic acid (DHA). EPA and DHA also serve as substrates for COX and 5-LO. They may thereby suppress the proinflammatory activities of AA both competitively and through the synthesis of products with less inflammatory or even antiinflammatory activity. 12-LO leads to 12-hydroperoxyarachidonic acid (12-HPETE) and 12-hydroxyarachidonic acid (12-HETE) formation, while 15-LO forms lipoxins A and B. The lipoxins possess antiinflammatory properties; together with $15dPGJ_2$ they may subserve roles in the resolution stage of acute inflammation. On the other hand, 5-LO generates the LT family of proinflammatory eicosanoids, such as LTB_4 and the peptidoleukotrienes LTC_4, LTD_4, and LTE_4. LTB_4 is a potent proinflammatory chemoattractant, drawing first neutrophils and later mononuclear cells to inflammatory sites. Peptidoleukotrienes are potent bronchoconstrictors. LTs are mediators of local vascular and cellular changes at sites of nonimmune inflammation and also in immune-mediated inflammatory conditions. Possible roles of LTs in conditions such as reactive airway obstruction in the horse and skin allergies in the dog have been investigated, and the use of 5-LO inhibitors as well as inhibitors of the actions of released LTs as therapeutic agents in immune-based inflammatory diseases has been researched (Marr, 1998).

Table 20.1 Characteristics, actions, and roles of COX-1 and its inhibition

A membrane-bound hemo- and glycoprotein of molecular weight 71 kDa, present in the endoplasmic reticulum
Encoded by a 22-kb gene
Constitutively expressed by cells in a wide range of tissues; involved in "housekeeping" functions
Enzyme concentrations are relatively stable, although small (two- to fourfold) increases occur in response to stimulation by hormones and growth factors
Responsible for generation of TxA_2 and PGs, e.g., PGE_2 and PGI_2 with local actions, such as gastroprotection, renoprotection, and hemostasis
Inhibited by classical NSAIDs which generally are nonselective for COX-1 and COX-2
NSAIDs, which may show some selectivity for inhibition of COX-1 relative to COX-2, include aspirin and ketoprofen.
Aspirin irreversibly inhibits COX-1 by covalent acetylation of amino acid Ser 530. Other NSAIDs inhibit COX-1 reversibly by excluding arachidonic acid from the upper portion of a long, hydrophobic channel

COX, cyclooxygenase; NSAID, nonsteroidal antiinflammatory drug; PG, prostaglandin.

Isoforms of Cyclooxygenase: Characteristics, Locations, and Roles

Cyclooxygenase-1 (COX-1)

COX-1 is a membrane-bound enzyme present in the endoplasmic reticulum (Table 20.1). It first cyclizes AA to form PGG_2 and then adds a 15-hydroperoxy group to convert PGG_2 to PGH_2. COX-1 is expressed constitutively in most tissues. It is involved in "housekeeping" functions, including blood clotting, regulation of vascular homeostasis, renoprotection, gastroprotection, and coordination of the actions of circulating hormones.

Cyclooxygenase-2 (COX-2)

COX-2 is both an inducible and constitutive isoform (Table 20.2) (Wooten et al., 2008). COX-2 synthesis is stimulated by proinflammatory cytokines, growth factors, lipopolysaccharide (LPS), and mitogens. The cloning, expression, and selective inhibition of canine COX-1 and COX-2 have been reported (Gierse et al., 2002). While most data support COX-2 as the isoform which generates pro- and antiinflammatory PGs at sites of inflammation, some data indicate a role for COX-1 as well (Smith et al., 1998; Bertolini et al., 2001).

Table 20.2 Characteristics, actions, and roles of COX-2 and its inhibition

Molecular weight of 70 kD and having 60% homology with COX-1 at the amino acid level
Has similar active sites to COX-1 for binding AA and NSAIDs, although the active site of COX-2 is larger and more flexible than that of COX-1 and can accept a wider range of structures as substrates
Encoded by an 8.3-kb gene
One of a family of primary response genes induced during inflammation and cell growth
Unlike COX-1 possesses a TATA box and binding sites for transcription factors, e.g., NFκB and a cyclic AMP response binding element in the promoter region of the immediate-early gene
A better competitor than COX-1 for AA released within the cell
Expression increased on exposure to lipopolysaccharide, cytokines (e.g., IL-1, TNF-α) immune and inflammatory stimuli
Present constitutively in monocytes, macrophages, pyloric and duodenal mucosa, endothelial cells, brain, dorsal horn cells of spinal cord, kidney, ovary, uterus, and ciliary body in the eye
Produces proinflammatory PGs (e.g., PGE_2) in the early stages of the acute inflammatory response and antiinflammatory PGs (e.g., $15dPGJ_2$) in the resolution phase
Down-regulated at the mRNA level by corticosteroids.
Exerts significant roles in certain cancers, Alzheimer's disease, and arthritides, and activation inhibits apoptosis (NSAIDs induce apoptosis)
Aspirin preferentially inhibits COX-1 (acetylating Ser 530), although higher concentrations also acetylate irreversibly Ser 516 on COX-2. Other NSAIDs compete reversibly with AA, the substrate for COX-1 and COX-2 for the active sites on the enzymes
Specific and selective inhibitors of COX-2, the COXIBs, are antiinflammatory and analgesic and have better gastrointestinal tolerance than many nonselective COX inhibitors

AA, arachidonic acid; COX, cyclooxygenase; NSAID, nonsteroidal antiinflammatory drug; PG, prostaglandin.

History of NSAIDs

The antecedents of the modern range of NSAIDs were extracts of various plants, in therapeutic use for more than 3,500 years, and comprising particularly the leaves and bark of the willow tree. These contain salicyl alcohol in free form or as glycosides such as salicin. The antiinflammatory properties of willow extracts were described by Dioscorides in his pharmacopoeia in the first century AD, as follows: "the leaves being beaten small and dranke with a little pepper and wine doe help such as are troubled with the Iliaca Passio (colic) … the concoction of ye leaves and barke is an excellent fomentation for ye gout." The Rev. Edward Stone described, in 1795, the antipyretic properties (cure of agues) of the willow noting, "as this tree delights in a moist or wet soil, where agues (fever) chiefly abounds the general maxim that many natural remedies carry their cures along with them or that remedies lie not far from their causes was so very apposite to this particular case that I could not help applying it." The "like cures like" concept was fashionable at that time, and persists in the nonscience of homeopathy to this day.

Discovery of salicyl alcohol/ salicylic acid as the active principles of plant extracts led to the use of sodium salicylate as the first synthetic NSAID in 1875 and then to the introduction of the acetyl ester of salicylic acid (aspirin) in 1898. By the sixth decade of the 20th century, aspirin, cinchophen, phenylbutazone, dipyrone, and isopyrin were, for several years, the commonly used NSAIDs in veterinary therapy. In the 1970s, flunixin was introduced and subsequently many novel NSAIDs have received marketing authorizations. Over the last 20 years in particular, there have been intensive searches for novel agents within the NSAID class, stimulated by several factors.

First has been the recognition that animals feel and suffer pain in a manner similar to the human animal. The welfare benefit of controlling animal pain is widely recognized. Second, it has been recognized that available drugs of the NSAID class, while commonly very efficacious, do not consistently in all animals or in all circumstances provide adequate levels of analgesia, especially when pain is severe. Third, the need to improve safety margins, notably in relation to gastrointestinal (GI) tolerance of NSAIDs, but also to ensure renal safety and to avoid uncontrolled hemorrhage, has been acknowledged. Most NSAIDs are clinically safe when used at recommended dose rates. However, there are several qualifications: there are equine examples (see Sections Additional actions of NSAIDs: gastrointestinal toxicity; renotoxicity; and hepatotoxicity) of narrow margins between clinically recommended NSAID doses and doses causing significant toxicity; side effects may be related to age and physiological/ pathological status (e.g., conditions and circumstances involving hypotension and hypovolemia predispose towards renotoxicity); NSAID toxicity may be idiosyncratic, occurring rarely but unpredictably, even with manufacturers' recommended dose rates. Therefore, safety concerns on older drugs have driven the search for novel agents.

Classification of NSAIDs, Chemical Structures, and Physicochemical Properties

Classifications based on chemical structure are of limited value because, despite minor differences between subgroups, all older NSAIDs have similar pharmacological actions (analgesic, antiinflammatory, and antipyretic), toxicity profiles, and clinical uses. Moreover, physicochemical properties are generally similar; almost all are weak organic acids (pKa in the order of 3.5–6.0) and of moderate to high lipid solubility (Veterinary Medicine Expert Committee on Drug Information, 2004).

The older (classical) NSAIDs are divided on the basis of chemical structure into two main groups: carboxylic acids and enolic acids, further divided into subgroups on the basis of chemical structure (Table 20.3, Figure 20.1). NSAIDs of the 2-arylpropionate group contain a single center of asymmetry; they are therefore chiral compounds. They are produced commercially as racemic (50 : 50) mixtures of the two optical enantiomers (R[−] and S[+]) and thus comprise a mixture of two drugs with differing pharmacokinetic and pharmacodynamic profiles.

Table 20.3 Chemical classification of classical NSAIDs

Carboxylic acids (R-COOH)	Enolic acids (R-COH)
Salicylates	**Oxicams**
Sodium salicylate[b]	*Meloxicam*[a]
Acetylsalicylic acid[a]	Piroxicam
Indoleacetic acids	Tenoxicam
Etodolac[a]	**Pyrazolones**
Indolines	*Phenylbutazone*[a]
Indomethacin	Oxyphenbutazone[c]
Thiopheneacetic acids	*Isopyrin (ramifenazone)*[a]
Diclofenac	*Dipyrone*[a]
Eltenac[a]	
2-Arylpropionic acids	
Carprofen[a]	
Ketoprofen[a]	
Vedaprofen[a]	
Ibuprofen	
Anthranilic acids	
Flunixin[a]	
Meclofenamic acid[a]	
Tolfenamic acid[a]	
Quinolines	
Cinchophen[a]	

[a] Drugs currently or previously licensed for veterinary use in some countries.

[b] Also a metabolite of acetylsalicylic acid.

[c] Also an active metabolite of phenylbutazone.

Novel SAID Classes

COX-2 inhibitors: The COXIBs are preferential or selective inhibitors of COX-2. They have differing structures to classical NSAIDs (Figure 20.1). Most are sulphones or sulphonamides, although robenacoxib is exceptional, being a carboxylic acid. The sulphones and sulphonamides are lipophilic compounds. Their relatively bulky structure limits COX-1 inhibition by steric hindrance. They have provided a significant advance in pain therapy (Wilson et al., 2004). The introduction of firocoxib into canine medicine for the therapy of canine OA comprised the first COX-2 selective drug for veterinary use (McCann et al., 2004), and others, including cimicoxib, deracoxib, mavacoxib, parecoxib, and robenacoxib, have followed.

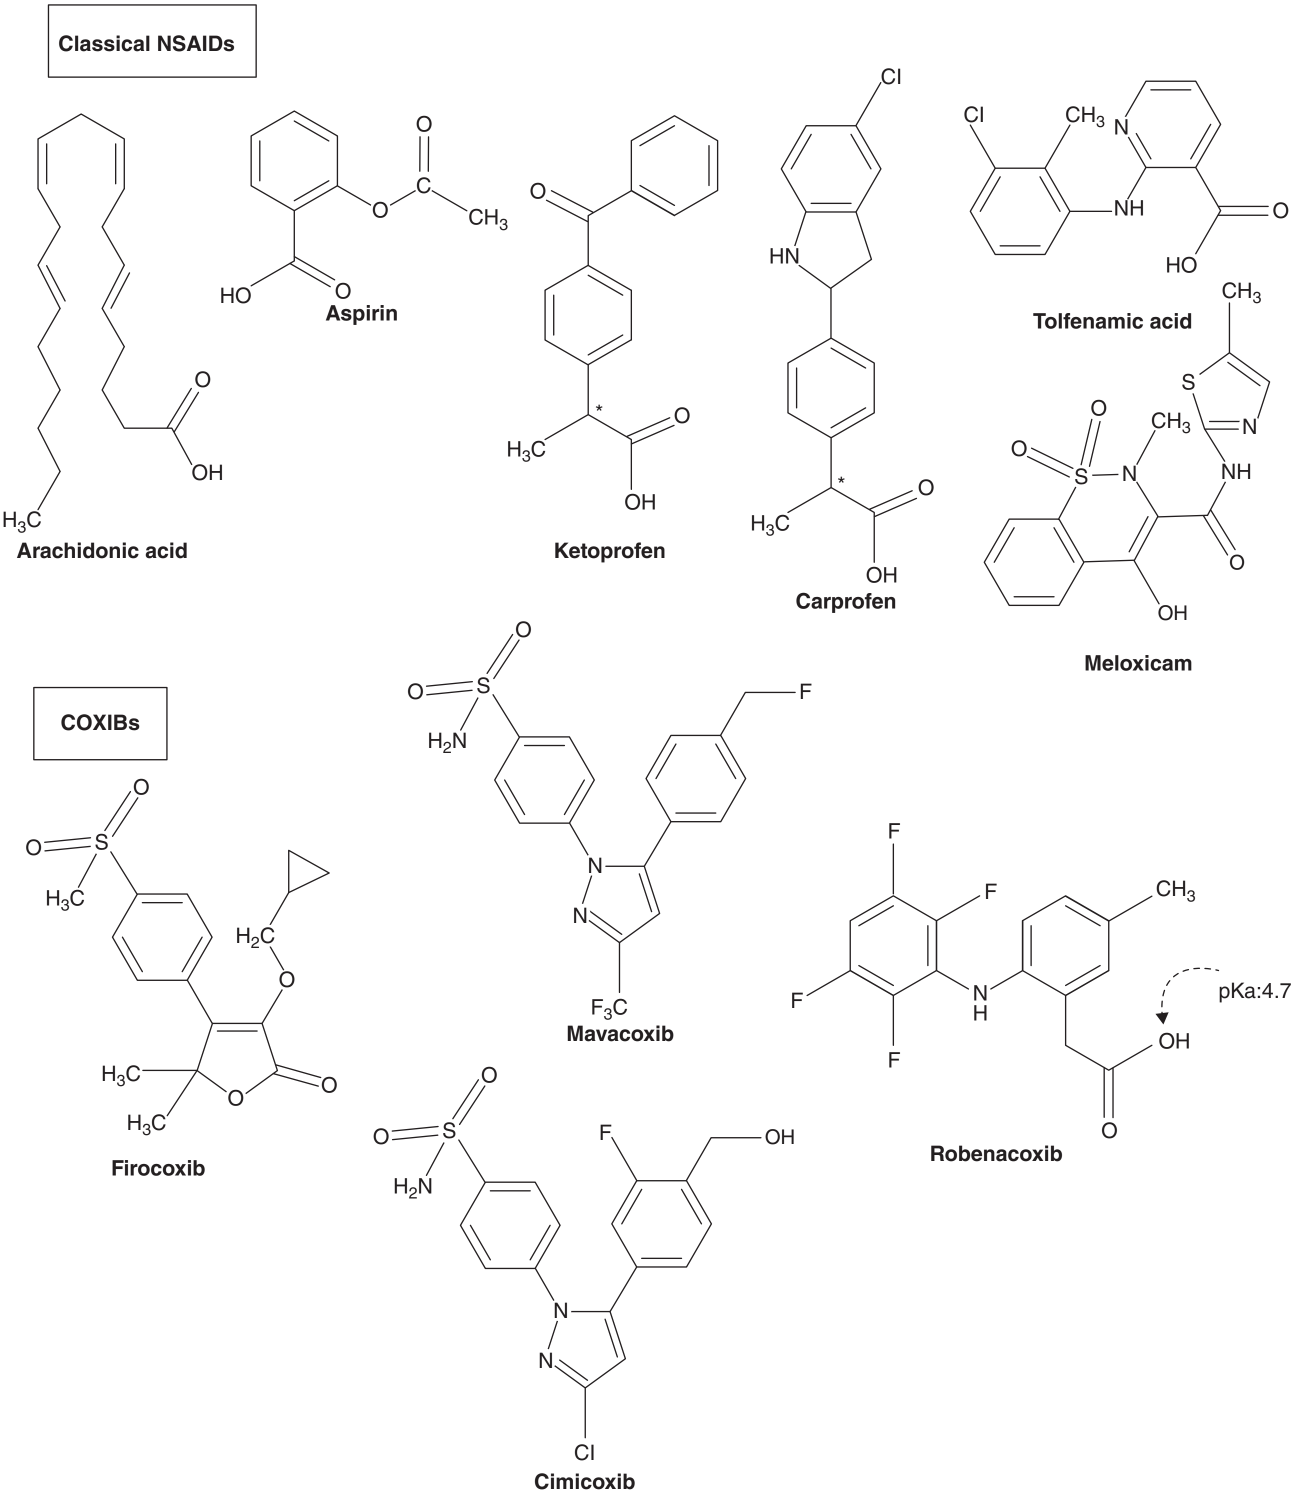

Figure 20.1 Structures of arachidonic acid and classical NSAIDs (aspirin, ketoprofen, carprofen, tolfenamic acid, and meloxicam) and COXIBs [firocoxib (methylsulfone), mavacoxib / cimicoxib (sulphonamides) and robenacoxib (carboxylic acid)]. * site of asymmetric carbon atom.

CINODS: COX-inhibiting nitric oxide donors (CINODs) are nitrosoesters of the older nonselective COX inhibitors (e.g., aspirin, phenylbutazone). The ester linkage is hydrolyzed in vivo to yield parent NSAID and the vasodilator nitric oxide (NO). The latter may enhance potency and increase gastric tolerance (Wallace et al., 2004). No drug of this class has been introduced into veterinary therapeutics.

Dual COX/5-LO inhibitors: The dual inhibitor tepoxalin was introduced into canine medicine (Argentieri et al., 1994) but drugs of this class have found only limited use in veterinary medicine.

Pharmacology of NSAIDs

NSAID Pharmacokinetics

Absorption

As lipid-soluble weak organic acids, classical NSAIDs are generally well absorbed when administered orally (Table 20.4), although rate and extent of absorption vary with species, gastric pH, dosing in relation to feeding, and gastrointestinal motility. In monogastric species, absorption from the stomach is favored by the Henderson–Hasselbalch ion trapping mechanism, which maintains a diffusion gradient for undissociated acid molecules between acidic gastric juice and plasma of pH 7.4. In ruminants, initial absorption from the four-compartment stomach and subsequent intestinal absorption creates the basis for a biphasic absorption pattern. In young ruminants, operation of the esophageal groove reflex is another mechanism accounting for double peaks in plasma concentration (Marriner and Bogan, 1979). Despite dilution in a large volume of rumen liquor (approximately 120 liters in an adult cow), bioavailability of phenylbutazone and meclofenamate was shown to be 50–60% in cattle (Lees et al., 1988a; Marriner and Bogan, 1979).

Table 20.4 General pharmacokinetic properties of NSAIDs

Generally good bioavailability in monogastric species after oral dosing. Absorption may be (a) delayed by binding to digesta (e.g., in horses and ruminants) (b) enhanced or reduced in the presence of food
Good bioavailability after parenteral (IM, SC) dosing
Penetrate blood–brain barrier to act centrally
High degree of plasma protein binding of all drugs (except salicylate) in all species limits passage from plasma into interstitial and transcellular fluids but *facilitates* passage into inflammatory exudate
Glomerular ultrafiltration and the renal excretion of parent drug markedly limited by high degree of plasma protein binding
Low volume of central compartment and low volume of distribution (with some exceptions, e.g., most COXIBs)
Elimination predominantly by metabolism in liver, usually to inactive compounds, but some metabolites are active, e.g., Phenylbutazone → oxyphenbutazone Aspirin → salicylate
For most drugs marked species (and possibly breed) differences in clearance and elimination half-life
Reduced clearance, increased half-life in neonates
Biliary secretion and enterohepatic recycling for some drugs

COXIB, cyclooxygenase inhibitor.

There are exceptions to the high bioavailability of NSAIDs after oral dosing. Bioavailability in horses was <5% for an oil-based formulation of RS-ketoprofen. However, when the pure drug substance was administered, bioavailability was of the order of 50% (Landoni and Lees, 1995). Another factor affecting absorption rate, of significance in the horse, is binding to hay (shown in vitro) and to digesta (demonstrated in vivo) (Lees et al., 1988b). Binding delayed the absorption of phenylbutazone and flunixin, accounting for double peaks in plasma concentration–time curves (Maitho et al., 1986; Welsh et al., 1992). In monogastric species, administration of NSAIDs with food is a common practice, as it may lessen irritant effects on the GI. As in horses, this practice is likely to delay absorption but to reduce absorption only moderately or not at all. However, the bioavailability of mavacoxib was higher in fed (87%) than in fasted (46%) dogs, while the converse was true for robenacoxib in both the dog (62 and 84%, respectively) and cat (10 and 49%, respectively) (Cox et al., 2010; Jung et al., 2009; King et al., 2013). As well as feed, other factors, including product formulation, may influence the rate and/or extent of absorption of NSAIDs. For example, aspirin is available in plain, water-soluble, film-coated, buffered, enteric-coated, and time-release formulations, with differing disintegration and dissolution rates.

Distribution

Most NSAIDs are highly bound to plasma protein (95–99% or greater). This limits passage from plasma into interstitial fluid. The volumes of the central compartment and distribution are generally low and values of 0.1–0.3 l/kg or less are common. There are exceptions, however, and moderate to high volumes of distribution have been reported for flunixin in cattle (but not in other species); for tolfenamic acid in the dog, calf, and pig; and for all sulphones and sulphonamide COXIBs (but not for the carboxylic acid derivative robenacoxib) in the dog. Contributing to these high distribution volumes for COXIBs is enterohepatic recirculation or a high level of extravascular accumulation/ tissue binding.

A potential therapeutic advantage of the high degree of plasma protein binding is accumulation of NSAIDs in inflammatory exudate. Since exudate is rich in albumin, which has leaked from the circulation, the binding of NSAIDs to albumin accounts for ready penetration into and persistence at sites of acute inflammation

Table 20.5 Examples of penetration into acute inflammatory exudate and transudate relative to plasma

Administered drug	Species	Dose (mg/kg)	AUC (µg·h/ml)		
			Plasma	Exudate	Transudate
RS-carprofen[b 1]	Horse	4.0	558 (R) 138 (S)	451 (R) 133 (S)	336 (R) 93 (S)
Flunixin[a 2]	Calf	2.2	11.8	27.6	7.0
Flunixin[a 3]	Horse	1.1	19.3	36.0	12.1
S-ketoprofen[a 4]	Horse	1.1	2.7	32.6	3.4
S-ketoprofen[a 5]	Calf	1.5	13.2	26.1	20.9
Phenylbutazone[a 6]	Horse	4.4	156	128	49
Phenylbutazone[a 7]	Donkey	4.4	19.2	8.0	5.0
Phenylbutazone[b8]	Calf	4.4	3604	1117	766

[a] Short plasma elimination half-life;
[b] longer half-life.
Data from [1]Armstrong et al. (1999a); [2]Landoni et al. (1995c); [4]Landoni and Lees (1996); [5]Landoni and Lees (1995); [6]Lees et al. (1986); [7]Cheng et al. (1996); [8]Arifah et al. (2002).

(Table 20.5). Exudate concentrations of NSAIDs often exceed those in plasma when drug body clearance is high and terminal half-life is short. Accumulation in exudate is a likely explanation for: (i) the maintained effectiveness of NSAIDs when plasma concentrations have decreased to low levels and (ii) why those NSAIDs with short elimination half-lives, for example flunixin, ketoprofen, vedaprofen, tolfenamic acid, and robenacoxib, may be effective with once-daily dosing. This longer duration of effect than predicted from plasma concentration–time profile is associated with the negative hysteresis described in in vivo studies, which indicate that maximal inhibition of PGE_2 synthesis in exudate occurs some time after peak drug concentrations in plasma (Giraudel et al., 2005b; Pelligand et al., 2012, 2014). The latter group reported elimination half-lives from feline exudate for S-ketoprofen and robenacoxib of 26 and 41 hours, respectively; corresponding values for blood were 1.62 and 1.13 hours after subcutaneous administration. Exudate PGE_2 concentration was reduced for 24–36 hours. In clinical OA dogs, the synovial fluid concentration of robenacoxib exceeded the IC_{50} for COX-2 for 16 hours; the corresponding time for healthy beagles was 10 hours (Silber et al., 2010).

For the 2-arylpropionate NSAIDs, enantioselectivity of distribution into exudate (Table 20.5) and synovial fluid (Armstrong et al., 1999a) has been demonstrated. This impinges on efficacy, as the two enantiomers exhibit pharmacodynamic differences as well (see Section NSAID pharmacodynamics: Inhibition of COX and 5-LO).

For those COXIBs based on sulphonamide or sulphone structures, the molecules are nonionized at physiological pH and volumes of distribution are high, whereas robenacoxib, a carboxylic acid, resembles most nonselective NSAIDs in having a low distribution volume.

A possible consequence of NSAID plasma protein binding is competition with other protein-bound drugs; theoretically this can lead to acute toxicity of either drug as the free concentration is increased. Nephrotic animals have reduced plasma protein concentrations and some authors have suggested that this may predispose to NSAID toxicity. However, in both of these circumstances, this will rarely be clinically significant, as the free concentration quickly falls, being subject to redistribution, metabolism, and excretion (Toutain and Bousquet-Melou, 2002).

The penetration of NSAIDs into milk in the absence of mammary gland infection is poor, milk concentrations being of the order of 1% or less of plasma total concentration. This results from the high degree of binding to plasma protein. Distribution into milk is also limited by the Henderson–Hasselbalch mechanism, as milk pH is less than that of plasma. In mastitis, however, penetration is likely to be increased from these low levels.

Excretion and Metabolism (Elimination)

As classical NSAIDs are weak organic acids, elimination in urine might be expected to vary with urine pH. In principle, ion trapping of the poorly lipid-soluble ionized moiety in alkaline urine will favor excretion in herbivores (horses and ruminants) but not in omnivores and carnivores (dogs and cats), as their urine is generally acidic. However, of over-riding importance for urinary excretion in all species is the high degree of plasma protein binding, which limits passage into glomerular ultrafiltrate to a small proportion of the total drug concentration in plasma. Hence, for most NSAIDs only small fractions of the administered dose are excreted in unchanged form in urine, irrespective of species and urine pH. This is illustrated by phenylbutazone excretion in the alkaline urine of horses; as a percentage of administered dose, the 24-hour excretion was 1.9 (Lees et al., 1987b). There is evidence for biliary secretion of some NSAIDs (e.g., carprofen) creating the basis for possible enterohepatic recirculation (Priymenko et al., 1993). Mavacoxib is also secreted in bile and its prolonged elimination half-life is due, in part, to repeated reabsorption of secreted drug but also to its high distribution volume (Lees et al., 2015).

Most NSAIDs are eliminated primarily by hepatic metabolism to less active (or inactive) phase 1 metabolites, which undergo conjugation phase 2 reactions to more polar, readily excreted conjugates. However, some drugs, such as aspirin and phenylbutazone, are converted to active metabolites, salicylate and oxyphenbutazone, respectively (Lees et al., 1987a,b). The deacetylation of aspirin is, in part, a spontaneous reaction, so that aspirin has a half-life of only several minutes in plasma. Therefore, salicylate accounts for most of the analgesic and antiinflammatory properties of administered aspirin, although aspirin itself accounts for the platelet-based antithrombotic actions. This is because aspirin blocks platelet COX covalently and irreversibly and therefore for the lifespan of the platelet. This permanent inhibition of platelet COX occurs after exposure for only a limited period, so that the short half-life of aspirin (approximately 9 minutes) in the horse does not limit platelet COX-1 inhibition for several days (Lees et al., 1987a).

Examples of elimination half-life are presented in Table 20.6. Interpretation of these values must take account of the fact that half-life is a hybrid variable, controlled by body clearance and volume of distribution.

Species differences in some pharmacokinetic variables are the rule rather than the exception for NSAIDs. For example, while plasma protein binding is almost invariably very high and volumes of distribution are low for classical NSAIDs in most species, clearance and terminal half-life vary markedly. The example of phenylbutazone is presented in Table 20.7. Aspirin, like phenylbutazone, provides a useful example of the impact of elimination on dosing intervals. The terminal half-life of its metabolite salicylate ranges from 32 minutes in cattle to 22–45 hours in the cat, in which species elimination is zero order (dose-dependent pharmacokinetics).

Table 20.7 Species differences in phenylbutazone pharmacokinetics

Species	Elimination half-life (h)	Clearance (ml/h/kg)
Man	72–96	—
Cow	42–65	1.24–2.90
Sheep	18	—
Goat	16	13.0
Camel	13	4.9–10.0
Horse	4–6	16.3–26.0
Dog	4–6	—
Rat	2.8–5.4	35–86
Donkey	1–2	170

The pharmacokinetics of the 2-arylpropionate subgroup of NSAIDs (carprofen, ketoprofen, and vedaprofen) is influenced by the possession of a single chiral center. There are therefore two mirror-image enantiomeric forms, R and S. The licensed products are the racemic (50 : 50) mixtures. Etodolac, though not a 2-arylpropionate, also possesses a single chiral center. The importance of NSAID chirality derives from the fact that the body is a chiral environment, whose cell membranes, macromolecules, and enzymes are based on D-monosaccharides and L-amino acids. Therefore, while NSAID enantiomers have virtually identical physicochemical properties, they do *not* have the same pharmacological properties in the body's chiral environment, as manifested by both pharmacokinetic and pharmacodynamic differences. Pharmacokinetic data based on "the total drug" concept must be viewed with alarm; such data comprises "highly sophisticated scientific nonsense" (Ariens, 1985) because racemic mixtures are simply combinations, in equal proportions, of two distinct drugs. Pharmacokinetic differences are reflected in clearance, elimination half-life, and plasma area under curve (AUC) ratios for the two enantiomers. As illustrated by

Table 20.6 Terminal half-life of NSAIDs (intravenous administration unless stated)

Species	Salicylate	Flunixin	Meloxicam	Carprofen S(+) R(−)	Ketoprofen S(+)R(−)	Naproxen	Tolfenamic Acid
Horse	1.0–3.0	1.6–2.1	3	16, 21	1.0, 0.7	5	7.3

carprofen, AUC ratios vary between species and may be as high as 4 : 1, despite the 1 : 1 ratio in the administered products (Tables 20.5 and 20.8).

Differences in pharmacokinetics for each enantiomer of chiral NSAIDs may arise in two ways. First, there are enantiomer differences in elimination, arising from differing rates of hepatic metabolism (Soraci et al., 1995). Second, for some drugs chiral inversion occurs in vivo. This, almost invariably, is unidirectional, comprising R to S inversion. Species (and breed) differences in the extent of chiral inversion of ketoprofen have been investigated (Table 20.9). There is also inevitable interanimal variation in the pharmacokinetics of NSAIDs. Table 20.10 presents data for firocoxib in beagles.

As well as interanimal and interbreed differences, a report on celecoxib in a colony of 245 beagle dogs revealed a *within*-breed difference; two subpopulations were identified, an extensive metabolizer (EM) phenotype for which mean half-life was 1.72 hours and clearance was 18.2 ml/kg/min, and a poor metabolizer (PM) phenotype for which corresponding values were 5.18 h and 7.15 ml/kg/min (Paulson et al., 1999). This example points to the possibility of significant genetic differences in clearance and terminal half-life of other NSAIDs. In fact, similar within-breed (beagle) pharmacokinetic differences (EM and PM phenotypes) have been described for cimicoxib (Jeunesse et al., 2013). Respective clearances were 0.31 and 0.11 l/h/kg. In a lameness model, duration of action was greater in the PM dogs. These authors also administered cimicoxib to dogs of four breeds; half-lives were of the same order of magnitude as those of the EM beagles.

In addition to species, inter- and intrabreed, and interanimal differences in NSAID pharmacokinetics,

Table 20.9 Species differences in extent of chiral inversion of R(−)- to S(+)-ketoprofen

Species	Inversion (% of administered dose)
Horse	48.8
Calf	31.7
Cat	22.4
Goat	15.0
Sheep (female, Dorset Cross)	13.8
Sheep (male, Corriedale)	5.9
Man	8.9

Table 20.10 Interanimal variation in firocoxib pharmacokinetics in the beagle dog[a]

Parameter	Mean	Range
C_{max} (μg/ml)	1.01	0.51–1.37
T_{max} (h)	2.63	0.79–4.45
AUC (μg/ml·h)	11.00	8.55–14.27
$T_{1/2el}$ (h)[b]	6.31	3.31–9.99

[a] Eight young beagles, both sexes: 5 mg/kg single dose administered orally (McCann et al., 2004).
[b] T1/2 values reported for other species are: 9–12 h (cat) and 30–40 h (horse).

there are inevitable intraanimal differences, arising from pathological or physiological state. Lascelles et al. (1998) reported, in dogs undergoing anesthesia, greater values of C_{max} (20.6 versus 11.0 μg/ml) and AUC (175 versus 115 μg/ml·h) when carprofen was administered postoperatively compared to preoperatively. In adult cows with an *E. coli* endotoxin-induced mastitis, values of AUC and clearance were 507 mg/l·h and 1.4 ml/kg/h for carprofen (Lohuis et al., 1991) whilst values for healthy cows were 294 mg/l·h and 2.4 ml/kg/h. Age may affect the pharmacokinetics of NSAIDs. Clearance is likely to be slower and half-life longer in neonates, as established for phenylbutazone in goats (Eltom et al., 1993) and as suggested for carprofen in young calves (Lees et al., 1996; Delatour et al., 1996) and for phenylbutazone in older horses (Lees et al., 1985). The effect of an endurance exercise on phenylbutazone pharmacokinetics in the horse was investigated by Authie et al. (2010) in relation to medication control; hepatic clearance was decreased, as also was volume of distribution, so that terminal half-life was not changed.

In the dog the clearance of COXIBs differs between the extremes of robenacoxib and mavacoxib (Table 20.11); 13.5 ml/min/kg (robenacoxib) and 0.045 ml/min/kg (mavacoxib) and respective half-lives were 0.63 hours and 17 days in laboratory (beagle or mongrel) dogs. In the cat the elimination half-life of robenacoxib was 0.78 to 1.49 hours and was independent of administration route – intravenous, oral, or subcutaneous (King et al., 2013; Pelligand et al., 2012). Mavacoxib biotransformation and renal excretion in the dog are very limited; elimination is predominantly by biliary secretion and excretion in feces, and enterohepatic recirculation contributes to the slow clearance and long terminal half-life. Lees et al. (2015) calculated that the maximum amount excreted daily in bile was less than 10% of the monthly dose. Based on dose normalized plasma AUC, the pharmacokinetics of mavacoxib administered orally did not differ between mongrel and beagle dogs and was proportional to dose over the range 2–25 mg/kg (Cox et al., 2010).

However, in population pharmacokinetic studies, in mainly elderly large breed dogs with OA, the mean elimination half-life of mavacoxib was longer (44 days) than the half-life of 17 days in laboratory dogs and in approximately 5% of OA dogs $T_{1/2}$ exceeded 80 days. This led to reduction in the dose predicted from laboratory dogs of 4 mg/kg to 2 mg/kg, with a dosing interval of 14 days between first and second doses and 28 days between subsequent doses and with a duration of therapy limited to 6 months (Cox et al., 2011). These authors reported body weight as the primary factor predicting clearance and distribution volume (both scaled by bioavailability) and with smaller effects of age and breed. In a clinical population of OA dogs, it was shown that apparent clearance and volume of distribution of robenacoxib were likewise proportional to body weight (Fink et al., 2013). Clearly, there is a need to conduct population pharmacokinetic studies in clinical subjects on other NSAIDs.

Parecoxib is an inactive prodrug, with a short half-life (0.42 hours) after intramuscular injection in the cat; it is converted in vivo to the active metabolite valdecoxib ($T_{1/2}$ = 8.52 hours; Kim et al., 2014).

Baert and De Backer (2003) provided valuable comparative pharmacokinetic data for sodium salicylate, flunixin, and meloxicam in five bird species, chicken, ostrich, duck, turkey and pigeon; species differences were marked.

Drug Residues

Regulatory authorities require that meat and milk withholding periods be established for NSAIDs licensed for use in food-producing species, including the horse. These are set on the basis of each drug's

Table 20.11 Comparative pharmacokinetics of five COXIBs in Beagle or mongrel dogs[a]

Variable (units)	Route	Mava coxib	Robenacoxib	Firocoxib	Deracoxib	Cimicoxib[c]	Cimicoxib[d]
Cl (ml/min/kg)[b]	IV	0.045	13.5	7.7	5	5.2	1.8
$t^1/_2$ (h or days)	IV	17 days	0.63 h	5.9 h	3 h	2.72 h	5.63 h
Vd_{ss} (l/kg)	IV	1.64	0.24	2.9	1.5	1.12	0.89
Plasma protein binding (%)	IV	>98	>98	–	>90	–	–
T_{max} (h) (fed dogs)	Oral	17.4	0.25	–	2.0	–	–
T_{max} (h) (fasted dogs)	Oral	67.4	0.5	1.0	–	–	–
F (%) (fed dogs)	Oral	87	62	–	>90	–	–
F % (fasted dogs)	Oral	46	84	101	–	–	–

[a] Data from Cox et al. (2010); McCann et al. (2004); Jung et al. (2009); Jeunesse et al. (2013); Deracoxib commercial literature.

[b] Clearance values can be compared with the value of 5.8 ml/kg/min defined by Toutain and Bousquet-Melou (2004) as a "low" value for dogs weighing 10 to 20 kg. This value emphasizes the particularly low clearance of mavacoxib.

[c] Extensive metabolizes.

[d] Poor metabolizes.

pharmacokinetic, metabolism, tissue depletion, and toxicological profiles, together with an appropriate safety margin. The relevant considerations for phenylbutazone have been reviewed (Lees and Toutain, 2013). This area is reviewed in Chapter 61 of this text.

NSAID Pharmacodynamics

Inhibition of COX and 5-LO

In addition to pharmacokinetic differences, a second basis for the variation in clinical response to NSAIDs between species, breeds, and individual animals is differences in their pharmacodynamics. This has been studied at several body levels: molecular, cellular, tissue, and whole animal, and can be considered in terms of the action–effect–response relationship (Table 20.12). The principal *action* is inhibition of COX, the enzyme with a pivotal position in the AA cascade; NSAIDs occupy the hydrophobic channel of COX, preventing AA access to its active site. This leads to the *effect* of inhibition of synthesis of proinflammatory mediators, including PGE_2 and PGI_2. The action and effect have been demonstrated with clinically achieved concentrations of many NSAIDs in several species (Lees and Higgins, 1985; Landoni and Lees, 1995, 1996; Landoni et al., 1995a,b,c; Cheng et al., 2003; Jones et al., 2002). The *responses* are the analgesic, antipyretic, antiinflammatory, antithrombotic, and antiendotoxemic properties of NSAIDs (Lees et al., 1986; Welsh and Nolan, 1994; Welsh et al., 1997; Nolan, 2001; Giraudel et al., 2005b). Current evidence suggests that a high level (80% or higher) of inhibition of PGs may be required to achieve good clinical responses.

Table 20.12 Principal action–effect–response relationships of NSAIDs

Actions	Inhibition of COX-1, COX-2, and, *for some drugs*, 5-LO
Effects	*COX inhibition*: reduced synthesis of eicosanoids with : proaggregatory and vasoconstrictor properties (TxA_2); antiaggregatory and vasodilator properties (PGI_2); proinflammatory properties (PGE_2, PGD_2, PGI_2); and antiinflammatory properties ($15\text{deoxy}\Delta^{12-14}PGJ_2$) *5-LO inhibition:* for dual inhibiting NSAIDs only, decreased synthesis of proinflammatory leukotrienes (LTB_4, LTC_4, LTD_4, LTE_4)
Responses	Reduction of raised body temperature (antipyretic), suppression of pain (analgesic/antihyperalgesic), decreased swelling (antiinflammatory) and *possibly* reduced rate of recovery in the resolution phase of acute inflammation – not clinically significant as far as known

COX, cyclooxygenase; LO, lipoxygenases; PG, prostaglandin.

Vane (1971) discovered that the principal mechanism of action of NSAIDs was inhibition of COX. A further advance occurred with the discovery of two COX isoforms, COX-1 and COX-2 (Kujubu et al., 1991; Xie et al., 1991). It was immediately recognized that most classical NSAIDs inhibit both isoforms, COX-1 inhibition producing toxic effects and COX-2 inhibition providing therapeutic effects. COX-1 was classified as a constitutive enzyme with physiological/ housekeeping functions, including gastro- and renoprotection and blood clotting leading to hemostasis. COX-2 was initially regarded solely as an inducible enzyme, up-regulated at sites of inflammation and responsible for producing proinflammatory mediators. Since 1991, much effort has been directed to identifying the following: which tissues express the two isoforms constitutively; the physiological and pathological roles of each isoform; the role of COX-2 induction at sites of inflammation and centrally; and the nature, incidence, and severity of side effects of drugs that inhibit one or both isoforms.

The overall roles of COX isoforms and the actions of NSAIDs, as perceived in 1991, have been modified as follows:

1) Warner and Mitchell (2003) have concluded that there are only two genes for COX enzymes, COX-1 and COX-2 and not a third, COX-3, as earlier postulated.
2) It is now recognized that COX-2 is a constitutive enzyme, present in stomach, brain, spinal cord, kidney, ovary, uterus, and ciliary body. Therefore, it has been postulated that complete inhibition of COX-2, especially over long periods, might be associated with such side effects as abortion, fetal abnormalities, delayed bone healing, delayed healing of soft tissue (including delayed ulcer healing), renotoxicity, and "adverse cardiovascular events." However, the now extensive clinical use over prolonged periods of COXIBs has been associated with a generally good safety profile. Nevertheless, COXIBs are not free of adverse effects on the GI and there remains controversy over the cardiovascular events associated with their clinical use, especially in human medicine when administered over prolonged periods. COX-2 is both constitutive and inducible in endothelial cells and its selective inhibition might disturb the endothelial PGI_2 (an antiaggregatory and vasodilator PG synthesized via COX-1 and COX-2) platelet TxA_2 (a proaggregatory and vasoconstrictor eicosanoid synthesized by COX-1) balance in the direction of platelet aggregation and vasoconstriction. The cardiovascular events in humans, which have been the subject of much public discussion, might reflect this imbalance. However, some reports have suggested an increased

cardiovascular risk in humans receiving long-term therapy with nonselective as well as COX-2 selective drugs. Epidemiological studies in animals reviewing such risks have not been reported.

3) Some reports indicate that COX-1 may contribute to the synthesis of proinflammatory PGs. Therefore, as well as COX-2 inhibition, inhibition of COX-1, as provided by the older nonselective NSAIDs, might be required for optimal efficacy. However, this concept is controversial and most experimental and clinical data suggest that selective COX-2 inhibitors are as efficacious as nonselective NSAIDs.
4) The introduction of a novel class of NSAIDs, the dual inhibitors, including tepoxalin, which inhibit two enzymes that use AA as a substrate, COX and 5-LO, has failed to make a major impact in veterinary medicine.

Efficacy, Potency, and Sensitivity of Inhibitory Actions of NSAIDs on COX Isoforms

As discussed in Chapter 4, the pharmacodynamic properties of any drug that define and quantify its action on a given tissue, organ, or enzyme are efficacy, potency, and sensitivity. Efficacy (I_{max}/E_{max}) is the maximal response a drug is capable of producing. It is important to the clinician because it defines, for example for a NSAID, the level of pain relief that the drug can provide. Potency is the drug concentration or drug dose producing a given level of response. It is usually determined as the concentration or dose producing 50% of maximal response (EC_{50} or ED_{50}) or, for drugs such as NSAIDs acting to inhibit an enzyme, potency is usually expressed as IC_{50}, although IC_{80} can be more useful. Potency is of less relevance than efficacy to the clinician, but it is critical to pharmaceutical companies when selecting a recommended dose rate for clinical use. NSAID concentration–response data are described by the sigmoidal E_{max} (Hill) relationship (Chapter 4) and the steepness of this relationship (N) determines sensitivity. For NSAIDs, slope may be shallow (less than 1) or steep (10 or greater) and in the latter circumstance the concentration–effect relationship becomes almost quantal (all-or-none).

In vitro assays have been used to determine I_{max}, IC_{50}, IC_{80}, IC_{95}, etc., and N of NSAIDs for each COX isoform. Depending on both the relative positions and slopes of the two curves, it is possible to determine selectivity, expressed, for example, as the ratio IC_{50} COX-1 : IC_{50} COX-2. The higher the ratio the greater the selectivity for COX-2. However, a high ratio (of say 50 : 1 or even higher) does not guarantee that at clinical dose rates a drug will inhibit COX-2 with no inhibition of COX-1 in vivo.

Based on selectivity, NSAIDs are classified as nonselective, COX-1 selective, or as preferential or selective (denoting increasing degrees of selectivity) for COX-2 (Table 20.13). Validating, confirming, and interpreting the data in Table 20.13 is problematic, as the scientific literature reports widely differing potency ratios (COX-1 :

Table 20.13 COX inhibitor classification[d]

Classification	Example	Comment
Preferential or selective COX-1 inhibitors	Aspirin, ketoprofen (cat)[a], vedaprofen[a], tepoxalin, flunixin (cow)	COX-1 inhibitory potency at least 5-fold greater than COX-2 inhibition
Nonselective COX inhibitors	S-Carprofen(horse)[b], flunixin, ketoprofen(dog, horse)[a], meloxicam[b], phenylbutazone, tolfenamic acid[b], vedaprofen[a]	No significant biological or clinical differences in concentrations producing COX-1 and COX-2 inhibition
Slightly or moderately selective COX-2 inhibitors[c]	S-Carprofen(dog, cat)[b], deracoxib, etodolac etoricoxib, meloxicam[b], tolfenamic acid[b], mavacoxib	COX-2 inhibition potency 5- to 30-fold greater than COX-1 inhibition Some antiinflammatory and analgesic activity may be obtained at concentrations inhibiting COX-2 but not COX-1 At higher concentrations, significant inhibition of COX-1 may occur
Highly or very highly selective COX-2 inhibitors[c]	Cimicoxib, firocoxib, robenacoxib, valdecoxib	More than 50-fold greater potency for COX-2 inhibition Limited inhibition of COX-1 in vivo (normally no GI ulceration or antiplatelet effects) even at maximum therapeutic doses

[a] Differing findings on selectivity from studies in various laboratories. Data in this Table based on whole blood assays.

[b] Species differences in degree of selectivity for COX-2.

[c] Selectivity and specificity depend on position and slope of COX-1 and COX-2 inhibition curves and therefore on the level of inhibition considered e.g., IC_{50}, IC_{80}, IC_{95}, etc.

[d] Ratios of inhibition (COX-1 : COX-2) are markedly affected by experimental conditions, e.g., isolated enzyme versus whole blood assay.

Table 20.14 RS-, S-, and R-carprofen COX-1 : COX-2 IC_{50} and IC_{80} ratios in whole blood assays in four species

Species	Enantiomer	IC_{50} ratio COX-1 : COX-2	IC_{80} ratio COX-1 : COX-2
Human[1]	RS	0.020	0.253

Table 20.15 IC_{50} values and IC_{50} COX-1 : COX-2 ratios for S- and R-carprofen enantiomers in the dog and horse (whole blood assays). Source: Data from Lees et al. (2000, 2004a).

Enantiomer	COX-1 IC_{50} (μM)	COX-2 IC_{50} (μM)	COX-1:COX-2 Ratio
Dog			
S(+) carprofen	176	7	25
R(−) carprofen	380	161	2.4
Horse			
S(+) carprofen	25	14	1.7
R(−) carprofen	373	137	2.7

COX-2) for individual drugs, even in a single species. The in vitro experimental conditions impact markedly on the COX-1 : COX-2 inhibition ratios, with higher values (i.e., higher selectivity for COX-2) commonly obtained when isolated enzyme, broken cell, or intact cell determinations in buffer are used in comparison with whole blood assays. The latter are accepted as the "gold standard" as they approximate most closely to conditions in the whole animal. Thus, Gierse et al. (2002) using isolated enzyme assays, reported for deracoxib an IC_{50} COX-1 : COX-2 ratio of 380 : 1 in humans and 1295 : 1 in the dog, whereas McCann et al. (2004) for the same drug, in a canine whole blood assay, obtained a ratio of 12 : 1. Likewise, Ricketts et al. (1998) reported a higher COX-1 : COX-2 ratio for rac-carprofen in isolated cell assays than those obtained in whole blood assays (Table 20.14).

NSAIDs with a chiral center have differing potencies and potency ratios for each enantiomer for COX-1 and COX-2 inhibition. Data for carprofen enantiomers are presented in Table 20.15. Studies using the racemate must be interpreted with great caution.

An additional consideration is the possibility (indeed likelihood) of species differences in NSAID potency for COX-1 and COX-2 inhibition and therefore differences also in COX-1 : COX-2 inhibition ratios. For example, on the basis of whole blood assays, carprofen would be classified as COX-1 selective or preferential in humans, nonselective in the horse, and COX-2 preferential or selective in the dog and cat (Table 20.14). Additionally, there are differences in both potency and potency ratios for the two enantiomers, with S-carprofen being significantly more potent than R-carprofen in the horse and dog. Moreover, in vitro assays indicate the likelihood for carprofen of differing ratios for IC_{50} and IC_{80} inhibition in each of the species cat, dog, and human, because of lack of parallelism between the COX-1 and COX-2 curves. Likewise, for meloxicam in the cat, COX-1 : COX-2 inhibition ratios in a whole blood assay were 3.05 : 1 (50%), 21.4 : 1 (80%), and 192 : 1 (95%) (Giraudel et al., 2005a).

In whole blood canine assays, firocoxib and robenacoxib had IC_{50} COX-1 : IC_{50} COX-2 ratios of 384 : 1 and 140 : 1, respectively (King et al., 2010a) whilst the ratios in the cat were 171 : 1 to 502 : 1 for robenacoxib and 88 : 1 for valdecoxib (Pelligand et al., 2014; Kim et al., 2014). Based on IC_{20}COX-1 : IC_{80}COX-2 ratios, the selectivity of mavacoxib (1.92 : 1) and carprofen (1.95 : 1) in whole blood canine assays was virtually identical (Lees et al., 2015). King et al. (2010a) reported IC_{20}COX-1 : IC_{80}COX-2 ratios in the dog of 0.21 : 1, 0.46 : 1, 2.45 : 1, 5.28 : 1, and 19.8 : 1, respectively, for ketoprofen, meloxicam, S-carprofen, deracoxib, and robenacoxib. Corresponding ratios in the cat were 0.0052 : 1 (ketoprofen), 0.25 : 1 (meloxicam), and 4.23 : 1 (robenacoxib) (Schmid et al., 2010b).

A high level of COX-2 inhibition (80% of I_{max}) may be necessary to obtain clinically desirable levels of antiinflammatory and analgesic activity for most drugs. Integration of in vivo plasma concentration–time data with IC_{80} data for COX-2 generated in whole blood assays in vitro was reported by Giraudel et al. (2005a). They calculated that the recommended dose of carprofen in the cat should produce 50, 80, and 95% inhibition of COX-2 for periods of 72, 57, and 42 hours, respectively, after a single intravenous dose. Corresponding values for the clinically recommended dose of meloxicam in the cat were 23, 9, and 0 hours, respectively. On the basis of COX-1 : COX-2 inhibition ratios and plasma drug concentrations obtained with clinical dose rates, it is likely that (in contrast to the cat) carprofen inhibition of COX-2 is at most moderate in the dog and horse when administered at recommended dose rates, 4.0 and 0.7 mg/kg, respectively. This led to an early suggestion that carprofen may act, in part, by one or more non-COX mechanisms. On the other hand, COX-2 inhibition data suggest that optimal efficacy might be achieved with a lower dose than that recommended in the cat (Giraudel et al., 2005a).

In Vivo and Ex Vivo Determination of COX Inhibition and Correlation with Clinical End-points

Determination of pharmacodynamic parameters for NSAIDs in vivo or ex vivo has the advantage over in vitro methods in that conditions are more directly relevant to physiological/clinical conditions. Using a tissue cage model of inflammation (Higgins et al., 1984) it was suggested that tolfenamic acid, S-ketoprofen, and flunixin are nonselective inhibitors of COX isoforms with only small differences in degree of selectivity between species (Landoni et al., 1995a,b,c; Sidhu et al., 2005, 2006). However, in this model in the cat, ketoprofen was COX-1 selective, while robenacoxib was COX-2 selective; respective IC_{50} COX-1 : IC_{50} COX-2 ratios were 1 : 107 and 67 : 1 (Pelligand et al., 2014). Another example of species differences is provided by phenylbutazone. Lees et al. (2004b) reported that phenylbutazone plasma concentrations 15 times greater in cattle than in the horse produced *less* inhibition of COX-2 in the former species.

Toutain and coworkers (1994) undertook PK-PD modeling of NSAIDs in an equine model of inflammatory joint disease, using clinical indices to predict dosage schedules. Flunixin was more potent (lower IC_{50} values) and efficacious (I_{max}) than phenylbutazone. Concentration–response relationships for stride length for these drugs, and also for meloxicam (Toutain and Cester, 2004) were steep. Simulations predicted, for flunixin for stride length, virtually no response at a dose of 0.5 mg/kg, maximal response persisting up to 10 hours at 1 mg/kg and maximal response up to 16 hours with a dose of 2 mg/kg.

Based on PK-PD modeling and simulations in a model of soft tissue (paw) inflammation in the cat, Giraudel et al. (2005b) calculated dosages of meloxicam required to provide 50, 70, and 90% of maximal responses for a range of indices of pain and inflammation (Table 20.16). In this study, hyperalgesia was not only fully inhibited but was reversed to reveal an hypoalgesic response, in which the threshold for pain sensation exceeded the levels obtained before inflammation induction. Giraudel et al. (2009) reported data in the same feline model for robenacoxib. Average IC_{50} concentrations (ng/ml) corresponding to ED_{50}s were 96 (lameness), 365 (pain), and 371 (antipyresis). These concentrations produced 79–92% COX-2 inhibition and 2.2–6.3% COX-1 inhibition. In a paw inflammation model in the dog, Jeunesse et al. (2011) correlated IC_{50} values for plasma meloxicam concentration with the actions of antipyresis (210 ng/ml) analgesia (390 ng/ml) and vertical force on a force plate (546 ng/ml). These IC_{50} values required 80–90% ex vivo COX-2 inhibition and were associated with levels of COX-1 inhibition of 33–53%. In a urate crystal model of joint disease in the dog, ED_{50} doses of robenacoxib for weight bearing and inhibition of COX-2 were 1.23 and 0.52 mg/kg, respectively (Schmid et al., 2010a).

Table 20.16 Simulated doses of meloxicam required to provide 50, 70, and 90% of maximum responses in the cat in a model of soft tissue inflammation. Source: Data from Giraudel et al., 2005b.

	Meloxicam dose (mg/kg)		
End-point	ED_{50}[a]	ED_{70}[a]	ED_{90}[a]
Skin temperature difference	0.40	0.50	0.67
Pain score	0.30	0.36	0.45
Body temperature	0.24	0.29	0.39
Lameness score	0.26	0.32	0.42
Overall locomotion variable	0.28	0.33	0.43

[a] ED (mg/kg) is the meloxicam dose producing 50, 70, or 90% of the maximum possible average drug response that can be obtained with a single subcutaneous administration of meloxicam. The manufacturer's recommended dose is 0.3 mg/kg.

For 2-arylpropionate NSAIDs, S-enantiomers are generally more potent COX inhibitors than R-enantiomers. However, both enantiomers were claimed by one author to be analgesic (Brune et al., 1992). Moreover, in the pig, mechanical nociceptive testing in a kaolin-induced lameness model indicated a higher potency for R-ketoprofen (IC_{50} = 1.6 μg/ml) than for S-ketoprofen (IC_{50} = 26.7 μg/ml) (Fosse et al., 2011).

Lees et al. (2015) compared in vitro canine IC_{20}COX-1 (2.46 μg/ml) and IC_{80}COX-2 (1.28 μg/ml) for mavacoxib in whole blood assays with maximum and minimum steady state concentrations in typical clinical OA cases of 2.08 and 1.28 μg/ml, respectively, indicating that peak concentration did not exceed IC_{20}COX-1, while trough concentration was equal to IC_{80}COX-2. Similar correlations between mavacoxib IC_{80}COX-2 and clinical end-points were established in canine models of synovitis (Lees et al., 2015).

Central Sites and Mechanisms of Action of NSAIDs

NSAIDs exert central as well as peripheral actions (Dolan and Nolan, 2000). COX-1 and COX-2 are expressed constitutively in dorsal root ganglia, in spinal dorsal and ventral grey matter, and in nonneuronal cells including astrocytes (Svensson and Yaksh, 2002). Central COX-2 up-regulation, in response to inflammation at peripheral sites, leads to release of PGE_2, which lowers spinal depolarization thresholds, thereby increasing action potentials and repetitive spiking. PGE_2-induced neuronal effects involve central sensitization (comparable to that occurring peripherally) or "wind-up" (Malmberg and Yaksh, 1992). Thermal hyperalgesia induced by injection of carrageenan into the paw was suppressed by both intrathecal and systemically administered COX-2 selective drugs and by a COX-1 selective inhibitor administered systemically (Yaksh et al., 2001). Moreover, intraspinal administration of a COX-2 inhibitor decreased central PGE_2 concentrations and suppressed mechanical hyperalgesia (Samad et al., 2001). Thus, the central actions of nonselective and COX-2 selective NSAIDs contribute to their antihyperalgesic actions.

Additional Actions of NSAIDs

As well as inhibition of COX isoforms, NSAIDs possess many other actions at the molecular level (Table 20.17). These include inhibitory effects on signal transduction pathways (Weissmann, 1991). Several NSAIDs, including phenylbutazone and flunixin, inhibit leukocyte migration in in vitro assays (Dawson et al., 1987) but not in vivo. Likewise, actions such as inhibition of NFκB demonstrated in vitro with high concentrations (Bryant et al., 2003) may or may not occur with therapeutic concentrations in vivo.

What is not known is the extent (if any) to which these additional actions contribute to the therapeutic effects of NSAIDs, when administered at clinical dose rates and by recommended routes, as many literature reports describe in vitro studies in which drug concentrations may be classed as heroic. Nevertheless, some in vitro data do correlate with in vivo findings. For example, carprofen has been shown in vitro to stimulate the synthesis and retard the breakdown of cartilage matrix molecules, proteoglycans, by both chondrocytes and cartilage explants in culture (Benton et al., 1997; Armstrong and Lees, 1999b; Frean et al., 1999). This might explain some beneficial effects of carprofen in canine OA (Pelletier et al., 2000). However, the effects of carprofen enantiomers on cartilage proteoglycan synthesis were concentration dependent, higher concentrations inhibiting synthesis. Similarly, Brandt (1991) reported that salicylate inhibited cartilage proteoglycan synthesis in vitro.

Acetaminophen differs from other NSAIDs in acting principally centrally rather than peripherally. However, Aronoff et al. (2005) have demonstrated a peripheral action – on the peroxidase enzyme component of prostaglandin H_2 synthase; the latter comprises peroxidase and COX portions. Other mechanisms of action of acetaminophen have been proposed, including activation of descending inhibitory pain pathways. Acetaminophen is not antiinflammatory (at clinical dose rates) but is analgesic and safe in the dog at a dosage of 15 mg/kg administered every 8 to 12 hours (Papich, 2008).

Toxicity of NSAIDs

General Considerations

The capacity for synthesis of PGs is common to almost all cell types; they are ubiquitous compounds, associated with a range of physiological and pathophysiological functions, inhibition of which is the main basis for

Table 20.17 Possible mechanisms of action of NSAIDs

Inhibition of Cyclooxygenase in the Arachidonic Acid Cascade Leading to Blockade of Synthesis of Proinflammatory Mediators is the Principal Mechanism of Action	
Additional actions of some drugs	**Examples**
Inhibit 5-LO	Licofelone, tepoxalin
Inhibit prostanoid release from cells	2-arylpropionic acids, indomethacin
Inhibit IκB kinases or NFκB to block COX expression	Aspirin, carprofen, flunixin, indomethacin, diarylheterocycles (COXIBs)
Inhibit the actions of eicosanoids on their receptors	Fenamates e.g., tolfenamic acid
Inhibit the actions of bradykinin	Flunixin, ketoprofen, tolfenamic acid
Modulate the release of proinflammatory cytokines, e.g., IL-1, IL-6, TNF-α	Carprofen (IL-6), tepoxalin (IL-1, IL-6, TNF-α)
Stimulate nuclear receptors, e.g., PPAR-γ	Salicylates, 2-arylpropionic acids, arthranilic acids, indene acetic acids
Increase intracellular breakdown of ATP to adenosine	Salicylates
Modulate the synthesis of nitric oxide	Several drugs
Inhibit neutrophil chemotaxis and/or chemokinesis[a]	Vedaprofen, salicylates
Inhibit neutrophil activation, thereby preventing (a) Release of oxygen radicals e.g., superoxide (b) Release of both lysosomal and nonlysosomal enzymes	Flunixin, ketoprofen, piroxicam, tolfenamic acid
Increased synthesis and reduced breakdown of cartilage matrix (proteoglycans)	Carprofen

[a] Most NSAIDs inhibit leukocyte movement in a concentration-dependent manner in *in vitro* assays (Dawson et al., 1987) but clinically recommended doses *in vivo* usually do not inhibit leukocyte chemotaxis or chemokinesis.

NSAID toxicity as well as therapeutic effects. The most frequent and clinically significant side effects are the effects on the GI. The principal target organs and tissues for *potential* toxicity are:

- gastrointestinal irritation associated with vomiting (possibly blood stained) in monogastric species, ulceration and erosions, leading to plasma protein losing enteropathy and melena;
- renotoxicity including occasional acute renal failure;
- hepatotoxicity (cholestastic or parenchymal);
- inhibition of hemostatic mechanisms leading to hemorrhage;
- blood dyscrasias;
- delayed parturition;
- delayed soft tissue healing;
- delayed fracture healing.

It must be emphasized that clinical manifestations of toxicity do not occur in the great majority of animals receiving recommended dose rates of NSAIDs. It is in the nature of pharmacovigilance data that a proportion of adverse reaction reports will be incidental and not drug related, whilst some are due to overdosing or reflect drug interactions. On the other hand, a proportion of reactions to NSAIDs will not be reported. Therefore, it is important to: (i) consider the incidence (low) and severity (usually mild and/or transient) of side effects; and (ii) distinguish between side effects actually reported in clinical use and those postulated on the basis of the molecular actions of NSAIDs or predicted from experimental animal studies.

An important consideration for animals is the ready (over-the-counter) availability of certain NSAIDs to animal owners through pharmacies and other retail outlets. A possible consequence is severe toxicity, when poorly informed owners have limited knowledge of NSAID pharmacological and toxicity profiles. For example, in the cat the metabolite of aspirin (salicylate) is cleared slowly and has a long elimination half-life (Table 20.6), so that approximately *one-tenth* of a 300-mg tablet represents a *maximum* dose, which should not be administered more frequently than 48-hour intervals. Likewise, the cat converts acetaminophen (paracetamol) to toxic metabolites and should never be given to this species (Hjelle and Grauer, 1986). However, Papich (2008) has suggested that acetaminophen might be reevaluated for use in the dog. This would seem to be appropriate in that peripheral tissues such gastric and duodenal mucosae and the kidney are spared its toxicity. There was no apparent toxicity in the dog at single dosages of less than 100 mg/kg (Savides et al., 1984).

In light of the potential toxicity of NSAIDs, avoidance of use is recommended in animals which are: dehydrated/ hypovolaemic/ hypotensive; avidly retaining sodium (congestive heart failure, hepatic cirrhosis); have existing renal, hepatic, or cardiovascular conditions; have gastric ulcers, reduced gastric blood flow; and animals receiving some other drug classes, including corticosteroids (delay wound healing) and aminoglycosides and polymixins (potential for nephrotoxicity). Drug interactions have been reported in humans or in experimental animal studies: increased risk of convulsions with fluoroquinolones; inhibition of the hypotensive actions of beta-blockers; inhibition of the actions of furosemide and angiotensin converting enzyme inhibitors. Delayed clearance, longer half-life, and increased plasma concentrations in neonates are possible and this in turn might lead to toxicity unless dosage regimens are reduced, though data in this field are limited.

There has been much discussion on the length of a wash-out period when one NSAID is substituted for another (Papich, 2008). Providing the switch is being made for nontoxicological reasons (this would usually be poor clinical response), it is probably in general acceptable to commence dosing with the new drug after 24–48 hours, since for most drugs a once-daily dosing schedule is required to maintain therapeutic responses. For mavacoxib at least a 28 day wash-out interval is recommended, because of the long elimination half-life. With this exception, the available data do not support withholding the replacement drug for up to 7 days for animals in pain on ethical grounds (Papich, 2008). However, if the substitution is made because of actual or suspected toxicity of the first drug, an interval of five to seven half-lives might be appropriate to allow for elimination of some 97% of the drug and healing of damaged tissue.

Extensive preclinical safety studies in healthy animals and tolerability in clinical trials have established generally good profiles for COXIBs, although the data do not always indicate superiority to the classical nonselective COX inhibitors. In preclinical placebo-controlled studies, the administration of doses of mavacoxib and robenacoxib several-fold greater than clinical doses for several weeks or months have indicated low toxicity (King et al., 2010b, 2011; Lees at al. 2015). Whilst the ideal would be to conduct placebo-controlled clinical trials to establish tolerability, these are rarely conducted for good ethical reasons.

Gastrointestinal Toxicity

Reports of serious GI-related side effects of NSAIDs in clinical use are rare, but mortality can occur. This normally involves marked GI ulceration and erosion and loss of blood or plasma into the peritoneal cavity, with sufficient fluid loss to cause hypovolemic shock. Moreover, through disruption of the mucosal GI barrier, the GI microflora may gain access to the circulation, leading to endotoxic shock. NSAID-induced irritation in the stomach can lead to persistent emesis, with associated fluid losses, requiring therapy with proton pump inhibitors or selective H_2-receptor antagonists. Alternatively, misoprostol, a stable derivative of PGE_1, has been used in combination with NSAIDs.

The GI toxicity of NSAIDs is due, in part, to "local actions" on the stomach. For aspirin, this can arise from its low water solubility and the creation of a local hypertonic solution bathing the stomach mucosa. However, the irritant actions of NSAIDs can occur throughout the tract and after parenteral as well as oral administration. Ulcerogenic doses of NSAIDs reduce PG concentrations in the gastric mucosa leading to reduced production of bicarbonate-rich mucus secretion, which provides a protective, viscous, alkaline lining fluid. These effects of NSAIDs have been linked to inhibition of the cytoprotective effects of COX-1. COX-1/PG gastroprotection also involves decreased volume and acidity of gastric secretion and local vasodilation. However, knock-out mice in which the COX-1 gene has been deleted fail to develop mucosal ulcers. Moreover, in the rat, neither SC-540 (a selective COX-1 inhibitor) nor celecoxib (selective for COX-2) alone caused ulcers, but erosions were induced when they were given in combination (Wallace et al., 2000).

COX-2 expression is increased on the edges of gastric ulcers; leading to the synthesis compounds, which accelerate ulcer healing, possibly by increasing angiogenesis via inhibition of cellular kinase activity and upregulation of vascular endothelial growth factor in the gastric mucosa. There may be roles for both PGE_2 and $15dPGJ_2$ in ulcer healing. COX-2 inhibitors have been shown experimentally to delay ulcer healing (Bataar et al., 2002) but this seems not to be a significant problem clinically.

A role for neutrophils in NSAID-induced GI toxicity has been proposed; NSAIDs increase neutrophil adherence to the mucosal vascular endothelium. In addition, monoclonal antibodies, which block leukocyte adhesion, reduce the severity of NSAID-induced gastropathic effects. The gastropathy is also reduced in animals that are neutropenic. Neutrophil adherence to endothelium may contribute to mucosal injury by releasing oxygen-derived free radicals, proteases, and other compounds. Moreover, neutrophil adherence might cause capillary obstruction, resulting in reduced gastric mucosal blood flow and hypoxia. However, not all data support a role for neutrophils in NSAID-induced GI ulceration.

Another theory of NSAID-induced gastropathy implicates reduced formation of the free radical gas NO. There is reduction or abolition of gastric damage by NSAIDs when they are used as nitrosoesters (CINODs). The nitroso group acts as a NO donor in vivo. The increased leukocyte adherence to the mucosal vascular endothelium caused by NSAIDs does not occur with the nitroso derivatives. Additionally, released NO may, through its vasodilator action, increase gastric and intestinal mucosal blood flows directly, thereby inhibiting NSAID-induced ischemia and hypoxia. Another proposed basis for NSAID-induced gastrotoxicity is diversion of substrate (AA) towards LO enzymes and the formation of products adversely affecting gastric mucosal integrity. Clearly, many factors may be involved.

An approach commonly employed to minimize GI irritation is to administer NSAIDs in feed or with water, to reduce drug concentration in contact with the GI mucosa. In addition, the site of NSAID-induced GI ulceration in the horse involves a specific interaction with feed. When administered with hay or horse nuts, phenylbutazone and flunixin bind to feed (Lees et al., 1988b). This limits absorption from the upper GI, as binding to feed is of the order of 98 and 70%, respectively. When the fibrous component of feed is partially digested in the large intestine, bound drug is released and becomes available not only for delayed absorption but also to exert a local irritant action. This probably explains the high incidence of lesions in the distal parts of the GI when high doses of phenylbutazone are administered to horses (Snow et al., 1979; Lees et al., 1988b).

Early reports described extensive erosions throughout the GI associated with a protein losing enteropathy and high mortality in ponies receiving oral phenylbutazone and ketoprofen doses only moderately in excess of those then recommended for clinical use (Snow et al., 1979; Lees et al., 1983; Taylor et al., 1983; MacAllister et al., 1993). There is a steep dose–effect relationship for the toxicity of phenylbutazone in the horse. Reports that ponies are more susceptible to the toxic effects of phenylbutazone than larger equine breeds have not been confirmed. Other manifestations of phenylbutazone toxicity in the horse include neutropenia, bone marrow suppression, parenchymal hepatotoxicity, and necrotizing phlebitis of the portal vein (Lees et al., 2003; Murray, 1985). Oral dosing of flunixin for 5 successive days at the recommended dose rate also reduced plasma total protein and albumin significantly in the horse (Lees and Higgins, 1985). Carprofen, on the other hand, has a wider safety margin in this species.

Using clinically recommended dose rates in the dog, the greatest incidence and severity of GI-related side effects were reported for flunixin and ketoprofen, while carprofen and firocoxib were better tolerated (Luna et al., 2007; Steagall et al., 2007). Carprofen is less likely than many other available agents to cause GI irritation in the horse and dog (Lees et al., 2004a), possibly arising from its selectivity for COX-2. It is likely that improved GI tolerance is also a property of COXIBs (cimicoxib, deracoxib, firocoxib, mavacoxib, parecoxib, and robenacoxib). Possible additional factors contributing to good GI tolerance of COXIBS are very short half-life plus rapid clearance from the central compartment (robenacoxib), once-monthly dosing, plus limited daily exposure from biliary secretion (mavacoxib) and inactivity of the parent drug (parecoxib converted to valdecoxib).

Overall, the human literature indicates a better GI safety profile for selective COX-2 inhibitors in comparison with nonselective inhibitors (Lanza et al., 1999; Hawkey et al., 2000) and valdecoxib and lumiracoxib provided similar levels of gastroduodenal tolerability to placebo treatments (Goldstein et al., 2003; Rordorf et al., 2003). However, in both humans and animals, COX-2 selective drugs are not free of GI-related side effects at high dose rates. For example, for firocoxib in healthy dogs at five times the recommended daily dose for 3 months, toxic signs included inappetence, emesis, duodenal ulcers, lipid accumulation in the liver, and vacuolization in the brain. However, emesis and duodenal ulcers did not occur with three times the recommended dose, administered daily for 6 months. Puppies aged 10–13 weeks were more susceptible than dogs aged 6–12 months (Steagall et al., 2007). Field trials in dogs reported a GI safety profile for mavacoxib equal to or possibly better than carprofen (Payne-Johnson et al., 2015).

Despite their potential for GI toxicity, NSAIDs as a group have generally good safety profiles, when administered at recommended dose rates in clinical subjects (KuKanich et al., 2012). Gastric adaptation in dogs may account at least partially for this (Papich, 2008). Components of this adaptation include increased gastric blood flow, reduced inflammatory cell infiltrate, and increased mucosal cell regeneration. When GI ulceration has occurred from any cause, COX-2 is rapidly induced; the enzyme generates cytoprotective prostaglandins. As predictable, COX-2 inhibitors inhibit the healing of preexisting ulcers in experimental rodent and canine studies. Selective COX-2 inhibitors are therefore unlikely to cause ulcers at recommended dose rates but they might delay the healing of preexisting ulcers (Wooten et al., 2008, 2010). Further studies are required.

Local Irritancy

Some NSAIDs may cause tissue necrosis after injection by nonvascular routes, for example phenylbutazone is formulated as a high-strength solution, whereas other NSAIDs such as carprofen and meloxicam have been specifically formulated for intramuscular administration.

Renal toxicity

Nephrotoxic effects of NSAIDs at recommended dose rates do not generally occur in healthy normotensive animals with free access to drinking water. Thus, pharmacovigilance studies indicated a very low incidence of nephrotoxicity in the dog for carprofen and mavacoxib; more than 800 dogs for the latter drug with treatment for 6.5 months (Payne-Johnson et al., 2015). In healthy cats, neither tolfenamic acid nor vedaprofen, administered once daily for 14 days, produced any demonstrable renotoxicity. However, PGs play subtle (but key) roles in renal physiology, regulating glomerular filtration, renin release, and tubular sodium reabsorption. Both isoforms of COX are present at several intrarenal sites with some differences between species, the functional significance of which is largely unknown. In the dog, COX-2 is expressed constitutively in the macula densa, thick ascending limb of the loop of Henle and interstitial cells, and also in humans in glomerular podocytes and the afferent arteriole. Chapter 24 should be consulted for details about renal pharmacology. COX products regulate renal homeostatic mechanisms in three main ways: glomerulotubular feedback to stabilize glomerular filtration rate (GFR); response to reduced water intake or increased water loss; and response to increased sodium intake. Potential side effects of NSAIDs include sodium retention (with accompanying edema), reduced GFR, and systemic hypertension.

Three aspects of the role of COX in the kidney, in relation to the use of NSAIDs, deserve particular consideration. First, COX products (possibly both COX-1 and COX-2 derived) are involved in maintaining renal blood flow and GFR in the face of reduced arterial pressure and/or fluid and sodium depletion, a phenomenon termed autoregulation. The macula densa (distal tubule cells which abut the afferent arteriole) senses high concentrations of chloride and secretes a signal (probably adenosine) to constrict the afferent arteriole and reduce GFR. When the macula densa senses low chloride concentrations, it secretes PGE_2, PGI_2, and nitric oxide, and these signal to modified afferent arteriole cells (juxtaglomerlular apparatus) to secrete renin, which leads to angiotensin I then angiotensin II synthesis, which in turn constricts the efferent arteriole, increasing GFR. Angiotensin II leads further to aldosterone secretion from the adrenal cortex and this hormone promotes sodium retention and potassium secretion. General anesthesia is a particular circumstance in which hypotension may arise from the cardiovascular actions of premedicant, induction, and maintenance agents, and this may be compounded by losses of blood and insensible water losses during surgery.

Second, under conditions of water deprivation, COX-2 in the renal medulla is up-regulated. If, under water deprivation conditions, NSAIDs are administered, interstitial cells undergo apoptosis, potentially leading to renal papillary necrosis. Third, the thick ascending limb of the loop of Henle transports some 25% of filtered sodium. These cells express COX-2 and release PGE_2. Feeding high concentrations of sodium up-regulates COX-2 in the medullary portion of the thick ascending limb. Administration of NSAIDs blunts the normal natriuretic response, with increased tendency to edema formation. However, the clinical relevance of this mechanism in veterinary medicine is unknown.

Blockade of the renoprotective actions of intrarenally released PGs explains the nephrotoxic effects of NSAIDs, and there were several early reports of acute renal failure with recommended doses of drugs such as flunixin, following recovery from anesthesia in the dog. Some authorities recommend restriction for some NSAIDs to postoperative administration, when blood pressure has been restored to normal and fluid losses have been replaced. Despite these considerations, an experimental study in healthy beagle dogs revealed no adverse effects on renal function of oral meloxicam, when the animals had been rendered hypotensive during anesthesia (Bostrom et al., 2006). Likewise, carprofen did not alter renal function in healthy dogs anesthetized with propofol and isoflurane (Ko et al., 2000). However, Forsyth et al. (2000) reported 26–34% reduction in GFR after surgery (routine castration) in dogs premedicated with carprofen or ketoprofen and then anesthetized with isoflurane. Oral daily administration of vedaprofen and tolfenamic acid in healthy cats produced no demonstrable renotoxicity (Khwanjai et al., 2012). Reports of renal papillary necrosis in horses receiving clinical dose rates of phenylbutazone or flunixin appeared in the 1980s, when horses on NSAID therapy also had restricted access to water.

Murine knock-out studies suggested that COX-2 is crucially involved in kidney maturation (Dinchuk et al., 1995). There is therefore potential concern on the use of NSAIDs in pregnancy as well as in neonates. In addition, very young animals are likely to have immature mechanisms of elimination (both renal and hepatic) of drugs, including NSAIDs. Therefore, in physiological or pathological conditions of hyponatremia, fluid depletion, and hypotension, and in disease states such as diabetes mellitus and diminished adrenocortical function, COX isoforms may maintain renal perfusion, GFR, and tubular function. All NSAIDs have the potential, in these conditions, to cause edema, reduced GFR, hyperkalemia, and hypertension. Moreover, in man, rofecoxib interfered with antihypertensive drugs, such as ACE inhibitors, angiotensin receptor blockers, and β-adrenoceptor blockers, which exert their actions, in part, through the renal vasodilator actions of PGs. Similarly, NSAIDs can interfere with the actions of loop diuretics, such as furosemide ; chronic treatment of dogs with furosemide plus carprofen or etodolac produced a reversible reduction in GFR (Surdyk et al., 2012). Potential toxicity from the combined use of NSAIDs with known nephrotoxic drugs, such as aminoglycoside and polymixin antimicrobial drugs, should be borne in mind. Moreover, dogs and cats developing chronic kidney disease are commonly elderly with multiple problems, including OA, requiring NSAIDs for pain relief. Particular care may be required in such patients, although definitive epidemiological data are lacking. Up-regulation of COX-enzymes in cats with chronic kidney disease in all areas of the kidney examined has been demonstrated (Suemanothan et al., 2009) but there was no association between proteinuria or progressive kidney disease and the magnitude of COX enzyme expression, suggesting that COX enzyme up-regulation may not be linked to progressive kidney disease in the cat.

Hepatotoxicity

Liver toxicity is rare in animals treated with clinical dose rates of NSAIDs. However, parenchymal hepatotoxicity has been described for phenylbutazone in the aged horse (Lees et al., 1983), possibly as a consequence of increased blood levels in older subjects (Lees et al., 1985). Cholestatic toxicity has also been described in the horse treated with phenylbutazone. Acute hepatic necrosis is a rare complication of carprofen in the dog, with a likely predisposition of the Labrador and related breeds (MacPhail et al., 1998). When therapy was discontinued in the dog, resolution of biochemical-associated liver changes and clinical signs occurred. An immune-based mechanism has been postulated. Hepatocellular damage in dogs has been reported with acetaminophen overdose.

Cardiovascular System and Blood Cells

The principal eicosanoids with local hormonal roles on blood vessels and blood cells are TXA_2 (a vasoconstrictor, proaggregatory agent, which is released from platelets and involved in blood clotting) and PGI_2 (a vasodilator, antiaggregatory, antiplatelet adhesive agent, released from endothelial cells, which prevents clotting in normal circulatory function). Platelet COX-1 is constitutive and endothelial cell COX comprises both isoforms. The TXA_2/PGI_2 system maintains a homeostatic balance, which can be disrupted by selective COX-2 inhibitors, potentially causing increases in blood pressure (through removal of the vasodilator influence) and a tendency toward clotting (through loss of the antiaggregatory effect). The potential for COX-2 inhibition to cause “cardiovascular events,” including thrombus formation and myocardial infarction, which may be life threatening, has been the subject of considerable debate in human medicine. Even in man, however, for whom very large-scale clinical trials have been undertaken, the situation is unclear. While several studies indicate an increase in relative cardiovascular risk in patients receiving selective COX-2 inhibitors, adverse cardiovascular effects are generally not apparent until continuous treatment has been given for periods of 18 months or longer. Furthermore, in one study, the greater relative risk with rofecoxib compared to naproxen was ascribed to a possible protective action of naproxen (which may be a preferential COX-1 inhibitor) rather than deleterious effects of the COX-2 inhibitor.

The adverse cardiovascular effects of selective COX-2 inhibitors in humans are dose related and there may be no significant increase in relative risk at low dose rates (Ray et al., 2002). Moreover, some studies have shown an increase in relative risk for cardiovascular effects for nonselective NSAIDs. Others have failed to demonstrate any increase in risk; a metaanalysis of eight OA trials indicated similar rates of thrombotic cardiovascular events with placebo, nabumetone, rofecoxib, and comparator nonselective NSAIDs, which included ibuprofen and diclofenac (Reicin et al., 2002).

The relevance of these human studies for veterinary species is unclear. The dog (but not the cat) is relatively resistant to thromboembolic diseases. Therefore, while the potential for adverse cardiovascular effects in veterinary patients must be borne in mind, veterinary experiences indicate a risk–benefit relationship in favor of benefits.

Among NSAIDs, aspirin is a special case, because of its irreversible action and the inability of platelets, being anuclear, to synthesize new COX-1. The potential for inhibition of hemostasis and prolonged bleeding time must therefore be borne in mind when aspirin is used therapeutically, even at low dose rates, and when other NSAIDs are used at high dose rates. In the horse, aspirin's antiplatelet action is manifested by virtually complete inhibition of TXA_2 synthesis for up to 1 week after a single dose, yet the terminal half-life after intravenous dosing is only 9 minutes (Lees et al., 1987a). This prolonged action might be due to inhibition of COX-1 in bone marrow megakaryocytes as well as circulating platelets. In humans, there is concern that concomitant administration of aspirin (for its antithrombotic effects) and other NSAIDs (for their analgesic, antiinflammatory effects) may result in interference with aspirin's antiplatelet actions (MacDonald and Wei, 2003). This might occur as a consequence of the very short half-life of aspirin, combined with NSAID prevention of aspirin entry to the COX-1 active site. In the dog, phenylbutazone was linked in early studies to blood dyscrasias (Tandy and Thorpe, 1967; Watson et al., 1980). It is not known whether these were dose-related or idiosyncratic, but blood dyscrasias are also associated with high doses of phenylbutazone in the horse. Early studies indicated marked depression of the bone marrow in cats receiving aspirin or phenylbutazone; in retrospect, it seems likely that the doses used were much greater than those required for clinical efficacy and may represent the effects of gross overdosage (Larson, 1963; Carlisle et al., 1968).

Acetaminophen has good GI tolerance but is toxic to the cat, in which species it is metabolized to oxidative compounds with cytotoxic properties. The metabolites overwhelm the glutathione scavenging system, resulting in methemoglobinemia and, less commonly, centrolobular hepatic necrosis. Recommended antidotes are antioxidants, such as vitamin C or *N*-acetylcysteine (St Omer and McKnight, 1980). In addition, the H_2-receptor antagonist, cimetidine, a hepatic microsomal enzyme inhibitor, has been recommended to inhibit formation of the toxic metabolites (Jackson, 1982). Similar signs of toxicity may occur with high dose rates of acetaminophen in the dog (Hjelle and Grasser, 1986).

Bone, Tendon, and Ligament Healing

In COX-2 null mice fracture healing is impaired (Zhang et al., 2002). However, the roles of PGs in bone metabolism are complex; PGE_2, PGI_2, and TxA_2 first stimulate new bone formation by osteoblasts and resorption by osteoclasts through EP_2 and EP_4 receptors (Kawaguchi et al., 1995). Moreover, in response to particulate wear debris, COX-2 increased the concentration of several proinflammatory cytokines (TNF-α, IL-lβ, IL-6) and other osteotrophic factors. PGs are thus involved in inflammatory bone conditions, with release by osteoblasts following injury (Gajraj, 2003; Gerstenfeld et al., 2003).

COX-1 is present constitutively in osteocytes, osteoblasts, and osteoclasts, but it is COX-2 mRNA levels that are raised and PGE_2 synthesis increased in the early stages of bone healing. Rodent studies have demonstrated reduced fracture healing in response to nonselective and COX-2 selective COX inhibitors (Simon et al., 2002; Goodman et al., 2003). These effects are reversible if dosing is not prolonged.

COX-2 is up-regulated only during the initial stages of bone healing and various orthopedic inflammatory and neoplastic conditions, such as canine and human osteosarcoma and canine pulmonary osteosarcoma (Radi and Khan, 2005). Reports of impairment of bone, tendon, and ligament healing by NSAIDs are conflicting, with some studies failing to show any deleterious effects. Radi and Khan (2005) concluded that, in animal models, NSAIDs retarded bone, ligament, and tendon healing, but the effects were confined to the early stages of healing, with no significant impact on long-term outcome. Indeed in one study, both COX-2 selective and nonselective inhibitors improved mechanical strength in the later phase of healing (Riley et al., 2001). There is a dearth of published clinical data in veterinary medicine in this field.

Soft Tissue Healing and Repair

There is potential for NSAIDs to affect the healing of soft tissues, given the postulated role of COX-2 products in the resolution phase of acute inflammation. Experimental data in mice both for (Laudederkind et al., 2002) and against (Blomme et al., 2003) a role for COX-2 in dermal wound healing have been presented. Data on wound healing relevant to species of veterinary interest are lacking.

Respiration

A subset of human asthmatic patients display signs of respiratory distress when administered aspirin (and in some subjects other NSAIDs also). This may be due to diversion of the substrate, AA, towards 5-LO and the increased synthesis of bronchoconstrictor LTs.

Skin

Occasional skin reactions to NSAIDs, including urticaria, rashes, and angioedema, have been reported. The mechanisms are unclear but, in some instances, a hypersensitivity reaction may be involved and possibly related to the high degree of binding to plasma proteins.

Reproductive System

Prostanoids are involved in ovulation, fertilization, and blastocyte implantation (Kniss, 1999). This is fully covered in Chapter 27 of this text. COX-2 null mice do not ovulate, and fertilization, implantation, and decidualization do not proceed normally. In early pregnancy, COX-2 is present in the uterine epithelium and is likely to be involved in ova implantation, angiogenesis, and labor. It has been suggested that COX-1 mediates the early stages of labor onset, involving uterine contractions and early stages of cervix dilation, whereas COX-2, induced by cytokines from the decidua, trophoblast, or fetal membranes, generates prostanoids to sustain myometrial contractions and cervical ripening leading to fetal expulsion. Experimental studies have indicated a role for PGE_2 in maintaining in utero the patency of the ductus arteriosus, and treatment with COXIBs postpartum leads to premature closure. Based on these roles of COX, various effects might be predicted from dosing with NSAIDs. In the testes, COX-2 is the main isoform and PGs formed include $PGF_{2\alpha}$, PGE_2, and PGD_2. The effects of NSAIDs on testicular function have not been extensively studied.

Nervous System

COX-2 is present constitutively, particularly in neonates, in neuron cell bodies and dendrites at several brain sites. Centrally, PGs are involved in body temperature regulation, hyperalgesia, and neuron development. PGs are not neurotransmitters but they modulate nerve transmission. In view of these roles of COX in CNS functions, it is perhaps surprising that so few significant central side effects are associated with NSAID use.

Therapeutic Uses of NSAIDs

Over the last two decades, the number of NSAIDs approved by regulatory bodies has increased significantly. This has been matched by a considerable increase in the extent of usage, driven by recognition of the wide range of circumstances in which the control of inflammation and pain is desirable for medical, welfare, and economic reasons. Products are available in both oral (tablets or liquids) and parenteral formulations. For some drugs, treatment may be continued for many months. Almost invariably, the dose interval is 24 hours. The main exception is mavacoxib, which is administered orally with an interval of 14 days between first and second doses and at 28 day intervals up to 6 months thereafter. This dosage schedule should improve dosing compliance by owners. Possible consequences of daily peaks and troughs of concentration (most NSAIDs) compared to sustained COX-2 inhibition throughout the interdose interval (mavacoxib) have been discussed (Lees et al., 2015).

Acute Pain and Inflammation

In animals, the presence of pain and its intensity can be difficult to recognize and quantify. Nevertheless, it is now acknowledged that animals “feel” pain (physiological) and we must assume that they also “suffer” pain (psychological) as do humans. Therefore, both subjective (e.g., semiquantitative scoring systems and visual analogue scales) and more objective (e.g., force plate) indices of pain/lameness have been used (Flecknell and Waterman-Pearson, 2000; Holton et al., 1998; Lipscomb et al., 2002). There is now widespread use of NSAIDs in all major veterinary species: (i) perioperatively, (ii) to treat acute trauma (e.g., road accident cases and equine/canine sports injuries), (iii) for a range of acute and chronic musculoskeletal conditions, and (iv) to treat the severe pain associated with colic in the horse (Balmer et al., 1998; Lascelles et al., 1995, 1998; Welsh et al., 1997; Robertson, 2005). In the latter condition, NSAIDs can mask the signs of colic, so that diagnosis of the underlying cause should be made prior to dosing. NSAIDs are used extensively to control acute pain associated with surgical and medical conditions (Table 20.18).

For the control of postoperative pain, NSAIDs may be as effective as opioids (Lascelles et al., 2007). However, NSAIDs are generally longer acting, do not possess the central nervous depressant/dependence side effects of opioids, and are subject to fewer legal restrictions. They are, therefore, commonly used as alternatives to opioids

Table 20.18 Conditions that may cause severe pain for which NSAID usage should be considered

Surgical conditions	Medical conditions
Orthopedic surgery	Bone tumors
Aural surgery	Disc lesions
Oral surgery	Otitis externa
Anal surgery	Various ophthalmic conditions
Upper abdominal surgery	Pancreatitis
Onychectomy	Acute moist dermatitis
	Equine colic

or to extend the duration of analgesia initiated by opioids. Preemptive analgesia with both drug classes (often in combination in multimodal drug approaches) has been widely advocated (Welsh et al., 1997). It involves administration pre- or early intraoperatively, both to enhance surgical conditions and also to control pain postoperatively (Lascelles et al.,1998). NSAIDs used preemptively include carprofen, meloxicam, tolfenamic acid, and the COXIBs. The preemptive concept derived from experimental studies in rodents but its benefit for NSAIDs in veterinary patients is less clear, although it is well supported by one study (Lascelles et al.,1998). The use of NSAIDs perioperatively can have the additional advantage of reducing edematous swelling and thus preventing wound breakdown. However, antiedematous doses, may be higher than those required for analgesia.

There is concern that the administration of NSAIDs before recovery from anesthesia might be associated with low incidence but life-threatening acute renal failure (see Section Renal toxicity). Of the agents in veterinary use, carprofen, meloxicam, and the COXIBs may be the agents of choice for pre- and intraoperative use. In clinical trials in the dog at recommended dose rates, analgesia with firocoxib was equal to or greater than that of carprofen or etodolac. For the control of pain and inflammation associated with both soft tissue and orthopedic surgery, robenacoxib was noninferior to meloxicam and had good tolerability in the dog (Gruet et al., 2011, 2013). For the control of postoperative pain in the cat, robenacoxib was superior to placebo (King et al., 2012) and superior to meloxicam for mainly soft tissue surgery (Kamata et al., 2012). For the treatment of pain and inflammation associated with musculoskeletal disorders in cats, robenacoxib was either noninferior or superior to ketoprofen, depending on the end-point monitored and both drugs displayed good tolerability (Giraudel et al., 2010; Sano et al., 2012).

Chronic Pain

NSAIDs are used to treat chronic pain, associated, for example, with the arthritides and cancer. In the horse and dog, OA is the most common indication for NSAIDs, to control short term flare-ups or for continuous management (Sanderson et al., 2009; Innes et al., 2010). Potential benefits are reduced pain, improved mobility and joint stability, reduction in muscle atrophy, and possibly reduced rate of disease progression. Many mediators are involved in joint conditions, leading to inflammation and increased angiogenesis of the synovial lining. The inflammation is particularly acute in canine rheumatoid arthritis compared to OA, and in OA acute inflammation is a more prominent component in the dog than in the horse. Some authors therefore prefer the term degenerative joint disease (DJD) in the horse.

The defining characteristics of OA are pain, stiffness, restriction of movement, catabolism of cartilage, and, in advanced cases, erosion of subchondral bone (Innes et al., 2010). Cartilage catabolism involves loss of matrix proteoglycans as breakdown exceeds neosynthesis. The roles of COX-2 in OA have not been fully elucidated, but the enzyme is up-regulated and PGE_2 concentrations in synovial fluid are increased in inflammatory joint diseases but not in DJD in the horse (May et al., 1992). Nevertheless, it is likely that PGE_2 is involved in the pain of OA and it also suppresses chondrocyte proliferation, increases IL1-β release (which is catabolic for cartilage), and inhibits chondrocyte aggrecan synthesis. It may therefore contribute to the loss of cartilage matrix.

Carprofen enhances SO_4 incorporation to stimulate the synthesis of proteoglycans by equine chondrocytes and cartilage explants in culture as well as reversing IL-1–induced suppression of proteoglycan synthesis by equine chondrocytes (Armstrong and Lees, 1999b, 2002; Frean et al., 1999). Carprofen exerts a similar action on canine chondrocytes (Benton et al., 1997). Whether these in vitro actions have significance for clinical subjects is not clear. However, a disease-modifying action of carprofen has been demonstrated in the dog in the Pond–Nuki model of OA (Pelletier et al., 2000).

Preclinical assessment of analgesic doses of NSAIDs for joint pain is often obtained using models providing intense but transient pain, for example, urate crystal–induced synovitis (Millis et al., 2002; Toutain et al., 2001b). While such models differ from clinical OA, it may be that they provide a major challenge to analgesic efficacy and are therefore justified for dosage selection for OA treatment. Toutain et al. (2001a,b) have carefully validated these models, comparing them (i) with data for COX inhibition in whole blood assays and (ii) against a Freund's adjuvant arthritis model in the dog.

Many controlled and randomized clinical trials have been undertaken to compare COXIBs with older drugs in dogs with OA for efficacy and tolerability. As regulatory authorities require, for licensing purposes, demonstration of noninferiority to a licensed drug, this has been the general outcome for efficacy (with occasional indication of superiority), whilst safety/tolerability profiles have been equal or superior to comparator products. Such findings have been shown for: firocoxib in comparison with carprofen or etodolac; mavacoxib in comparison with carprofen or meloxicam (Payne-Johnson et al., 2015; Walton et al., 2014); and robenacoxib compared to carprofen (Edamura et al., 2012; Reymond et al., 2012). Bennett et al. (2013) reported decreased lameness in OA dogs together with a reduction in synovial fluid C-reactive protein in response to robenacoxib. NSAIDs are used to treat some immunological diseases, such as systemic lupus and rheumatoid arthritis, where they may stimulate T-suppessor cells in their action against T-helper cells and autoantibody-producing B cells.

Antipyresis

NSAIDs lower body temperature in the presence of fever associated with microbial infections. The extent to which this is beneficial is unclear but human experience suggests improved feeling of well being. In animals, the antipyretic action of NSAIDs may encourage an earlier return to normal drinking and eating patterns and thereby aid recovery, when used concomitantly with antimicrobial drugs. Dipyrone is used only for its antipyretic properties but has been largely superseded by safer drugs; bone marrow toxicity is a potential concern with dipyrone.

Antihemostatic Actions of Aspirin

At clinically recommended dose rates, NSAIDs do not, as far as is known, markedly prolong bleeding times, although there are anecdotal reports that some prolongation occurs with some drugs. However, the action of aspirin on hemostatic mechanisms is unique in covalently acetylating COX-1, and inhibiting it irreversibly. Therefore, aspirin is the NSAID of choice as an antithrombotic drug, for example, in prophylaxis of aortic embolism in cats and in cats with hypertrophic cardiomyopathy to reduce the potential for thrombus formation and when a saddle thrombus of the aorta or iliac arteries has been diagnosed. In dogs with proteinuric glomerulonephritis, low-dose aspirin has been recommended for prevention of thromboembolic complications. The antithrombotic action of aspirin may also be of value in equine conditions, such as laminitis, navicular disease, and disseminated intravascular coagulation, although definitive studies are lacking.

Cancer

Epidemiological studies on human patients receiving long-term treatment with NSAIDs have indicated a potential beneficial effect against colon cancers. Overexpression of COX-2 in epithelial colon cells causes resistance to apoptosis and promotion of tumor growth by stimulating the production of growth factors and by angiogenesis; cancerous colon tissue has increased PGE_2 concentrations. A possible mechanism of the procancerous action of PGE_2 is transactivation of epidermal growth factor receptor, promoting growth of colonic polyps and cancers (Pai et al., 2002). Colon tumor cells (adenomas and adenocarcinomas) show increased COX-2 and decreased COX-1 expression at mRNA and protein levels compared with normal colon epithelial cells, and a therapeutic role for COX-2 inhibitors has been established in the prevention, treatment, and palliation of certain cancers. In dogs, PGE_2 concentrations were increased in osteosarcoma tissue compared to normal bone (Mohammed et al., 2001). Moreover, COX-2 upregulation occurs in colorectal tumors and polyps in the dog, canine transitional cell bladder carcinomas, and canine osteosarcomas (Mullins et al., 2004).

NSAIDs may reduce cell numbers in various cancers, and studies demonstrating that they directly induce apoptosis in neoplastic cells and inhibit angiogenesis provide possible mechanisms of action. Clinically, in canine prostatic carcinomas, carprofen and meloxicam increased median survival time and piroxicam, meloxicam, deracoxib, and firocoxib have been used in the treatment of transitional cell tumors in dogs; Knapp et al. (1992) reported a reduction in tumor size with piroxicam. In dogs with rectal polyps, piroxicam reduced polyp size and suppressed clinical signs (Knottenbelt et al., 2000). Pang et al. (2014a) identified antiproliferative and proapoptotic effects of mavacoxib on canine cancer cell lines and cancer stem cells in vitro. They also demonstrated a role for COX-2 in osteosarcoma initiation (Pang et al., 2014b). Wolfsberger et al. (2006) reported that meloxicam at low concentrations (1–10 μM) *increased* numbers of D-17 canine osteosarcoma cells in vitro after exposure for 3 days, whereas high concentrations (100 and 200 μM) exerted a marked antiproliferative effect. It should be noted that the maximum serum concentrations of meloxicam in the dog after therapeutic doses are 1.3 μM (oral dosing) and 2.1 μM (subcutaneous injection), and most of the drug is bound to protein (Busch et al., 1998).

In humans low-dose aspirin (81 mg daily), but not a higher dose (325 mg daily), reduced the adenomas occurring in colon cancer (Baron et al., 2003), but in another study the 325 mg dose of aspirin did suppress adenomas (Sandler et al., 2003). Neither the low nor the high dose is likely to produce significant and persistent COX-2 inhibition, whereas the antiplatelet COX-1 inhibitory actions are exerted at both the low and higher doses. Furthermore, much evidence correlates platelets to cancer spread. Nevertheless, low-dose aspirin (82 mg) does reduce colonic prostanoid synthesis by more than 50% and a higher daily dose (650 mg) produced no greater inhibition (Krishnan et al., 2001; Sample et al., 2002). Antiproliferative effects of COX inhibitors have been described in COX-negative cell lines, so that non-COX mechanisms of action are possible (Waskewich et al., 2002; Wick et al., 2002).

Mastitis, Metritis, and Endotoxemia

E. coli (acute and peracute) is a major welfare concern and source of economic mastitis loss in the dairy industry, involving reduced milk production, treatment costs, discarded milk, and mortality. As well as inflammation in the affected quarters, systemic signs include depression, fever, tachycardia, neutropenia, and inhibition of reticulorumen motility. Endotoxin causes the release or de novo synthesis of many inflammatory mediators and endotoxemia may be regarded as an acute inflammatory condition of the circulatory system. Endotoxic shock may be associated with a range of diseases in addition to mastitis, including equine colic, metritis, and septic peritonitis. Several reports in the 1980s indicated a therapeutic role for phenylbutazone and flunixin in equine endotoxemia (Moore, 1986; Moore et al., 1986) and for septic shock in dogs (Hardie et al., 1983). NSAIDs must be administered as soon as possible after onset of these conditions together with other supportive therapy.

For the treatment of acute mastitis and endotoxemia, systemically administered NSAIDs are used as adjuncts to antimicrobial drugs. For example, responses to carprofen therapy included lowering of rectal temperature, restoration of reticulorumen motility, and more rapid normalization of the clinical severity score in an *E. coli* model of mastitis (Vangroenweghe et al., 2005). These findings confirm the reports of previous workers for flunixin (Anderson et al., 1986a,b; Lohuis et al., 1989; Ziv and Longo, 1991), flurbiprofen (Lohuis et al., 1989; Vandeputte-Van Messom et al., 1987), indomethacin (Burvenich and Peeters, 1982), ketoprofen (Shpigel et al., 1994), phenylbutazone (Shpigel et al., 1996), dipyrone (Shpigel et al., 1996), and meloxicam (Banting et al., 2000). In addition to beneficial clinical responses, Anderson et al. (1986b) reported reduced PGE_2 and TxA_2 concentrations in the udder in response to flunixin; increased whey IgG1 and IgM concentrations were also obtained. Insofar as the effects of endotoxin are COX-mediated, it is likely that both isoforms are implicated. Therefore, a nonselective COX inhibitor may be the most rational therapeutic choice.

Systemically administered NSAIDs may be of less benefit in cases of mild or chronic mastitis. Pyorala et al. (1988) examined the influence of phenylbutazone and flunixin in cases of chronic subclinical mastitis. Neither drug influenced bacterial growth, somatic cell count, or inflammatory markers. However, Fitzpatrick (1998) reported that allodynia was abrogated by a single intravenous dose of flunixin. Further work is required to establish optimal dosage regimens for inflammatory conditions in cattle. Some studies have shown no beneficial effect of NSAIDs in reproductive disorders, such as retained placenta and postpartum endometritis (Konigsson et al., 2001). However, flunixin reduced the incidence of pyrexia in cows with either acute or subacute metritis (Amiridis et al., 2001). Uterine involution and onset of estrus occurred earlier in cows that received flunixin. It should be noted that the withdrawal time of flunixin should be increased from label recommendations when given to cows with severe clinical mastitis (Kissel et al., 2015).

Respiratory Diseases

Acute and potentially life-threatening inflammatory lung infections occur in calf and piglet pneumonias of viral, bacterial, or mixed etiology. Disease models and/or clinical trials have indicated positive responses to NSAID treatment; flunixin reduced lung consolidation scores in calves infected with P13 virus (Selman et al., 1984). However, other findings have been conflicting.

The effects of flunixin on lung lesions, postmortem lung weights (reflecting an antiedematous action) and clinical signs in an experimental bovine pasteurellosis model were investigated by Selman (1988). Benefits were apparent when used in combination with oxytetracycline. Anderson (1988) investigated a flunixin/oxytetracycline product in comparison with oxytetracycline alone in field cases of pneumonia. Reduction in coughing, return to normal food intake, and weight gain were better improved with the combination product and there were fewer relapses.

Other NSAIDs have been used as ancillary agents with antibiotics in the therapy of calf and/or piglet pneumonias. Not all studies have demonstrated clear benefits of NSAIDs, and the mechanism of any beneficial actions is not established. One may speculate that the antiinflammatory action may reduce pulmonary edema and improve lung function and respiratory gas exchange, while the antipyretic action may improve clinical status, so that animals begin to eat and drink. As cattle rely principally on respiration for temperature regulation, they may be stressed from infections causing pyrexia and hence benefit from the antipyretic actions of NSAIDs. The analgesic action of NSAIDs might also contribute to improvement in clinical status. As NSAIDs induce apoptosis, this may minimize release within the lungs of inflammatory mediators, which occurs when leukocytes are destroyed by viruses and bacteria. Carprofen, flunixin, ketoprofen, tolfenamic acid, and meloxicam possess marketing authorizations for use in the therapy of pneumonia in calves and/or piglets.

Ingestion of 3-methylindole in cattle causes a chemical toxicosis (fog fever) characterized by signs of respiratory distress, lung congestion, edema, and interstitial emphysema. Flunixin reduced respiratory rate and the extent of lung lesions, assessed by pathological and histopathological examinations, reducing the degree and severity of alveolar epithelial hyperplasia (Selman, 1988).

Calf and Piglet Scours

Infections of the GI in young calves and piglets are associated with high morbidity and, in the absence of effective treatment, possible mortality. Early studies suggested possible benefits from aspirin treatment. Jones et al. (1977) described the benefit of flunixin therapy in suppressing inflammation, reducing fluid losses in feces, and lowering morbidity and mortality in calf scours. Meloxicam is licensed for use in calf scours in combination with antimicrobial drugs.

Ophthalmic Uses

NSAIDs are used to treat conditions such as keratitis and scleritis by topical application; they do not inhibit reepithelialization of the cornea. Flunixin, phenylbutazone, and firocoxib have been used systemically in the management of nonulcerative keratouveitis and corneal ulceration in the horse. Aspirin and flunixin may be of value in intraocular surgery to minimize postoperative increase in aqueous humor protein concentration.

Neurodegenerative Diseases

COX-2 is up-regulated in the hippocampus and cortex in human subjects with dementia. PGs decrease neuronal function and accelerate neurodegeneration in patients with Alzheimer's disease (Hwang et al., 2002). Human epidemiological studies have indicated a lower incidence of Alzheimer's disease in subjects receiving a NSAID prior to the onset of neurological symptoms and on long-term NSAID therapy (Launer, 2003). This may be linked to their antiinflammatory properties; COX-2 containing inflammatory cells are present in the vicinity of amyloid-β plaques. However, there was no slowing of cognitive decline in patients with mild to moderate Alzheimer's disease receiving rofecoxib and naproxen over 12 months (Aisen et al., 2003). Stewart et al. (1997) reported relative risks of 0.4 and 0.65 for patients receiving NSAIDs for more than and less than 2 years, respectively. However, for acetaminophen the relative risk was 1.35. The mechanism of action of NSAIDs is unclear and does not necessarily involve COX inhibition.

Section 5

Drugs Acting on the Cardiovascular System

21

Digitalis, Positive Inotropes, and Vasodilators

Clarke E. Atkins and Marisa K. Ames

An understanding of the pharmacokinetic and pharmacodynamic characteristics of cardiac drugs is essential for veterinarians who treat cardiovascular disease. Cardiac disease is often severe and life-threatening events must be managed with these drugs. Also, states of cardiac dysfunction that are amenable to drug therapy are common in dogs and cats. This chapter considers some of the more important drugs used in therapeutic management of cardiac disorders, with focus on those that affect basic aspects of cardiovascular function, including positive inotropes, inodilators, and vasodilators. Antiarrhythmic drugs are covered in Chapter 22. Other classes of drugs that elicit prominent cardiac responses (e.g., adrenergic and cholinergic agents) are discussed in Chapter 8, while off-loading therapies, other than vasodilators and inodilators (i.e., diuretics) are discussed in Chapter 24.

Basic Aspects of Cardiac Function

The primary pathways by which the cardiovascular system can increase or decrease cardiac output, based on need, include changes in heart rate, adjustments in myocardial contractility, an intrinsic response of the cardiac muscle to changes in muscle length, and optimization of vascular size (vasodilation and vasoconstriction). This physiological (neurohormonal) control is via pressure sensors, the central nervous system, sympathetic and parasympathetic nervous systems (SNS, PSNS), and the renin–angiotensin–aldosterone system (RAAS). The control systems involved are of considerable importance to pharmacology because the net response of the heart and vascular system is to these regulatory systems and the drugs administered often provide their effect via stimulating or blunting these systems.

Intrinsic Regulation

Contractile response of cardiac muscle to a change in its own length is the primary mechanism whereby the heart adjusts its pumping activity under normal physiological conditions (Fozzard, 1976). When venous return increases, the contractile function in the healthy heart increases, thereby pumping an increased volume of blood into the arterial system. This fundamental capability of the heart to autoregulate its pumping capacity in response to end-diastolic filling is referred to as the *Frank–Starling law of the heart* (Frank, 1895; Starling, 1918). This force–length relationship is primarily a result of an increase in calcium sensitivity as the initial sarcomere length increases. The relationship between preload (end-diastolic filling) and cardiac output under basal conditions and under dominance by the sympathetic and parasympathetic nervous systems is shown in Figure 21.1.

Regulation by the Nervous System

The autonomic nervous system regulates the cardiovascular system mainly by adjusting heart rate, vascular volume, and myocardial contractility. Details concerning cardiac effects and mechanisms of action of the sympathetic neurotransmitter norepinephrine (NE) and the parasympathetic neurotransmitter acetylcholine (ACh) are found in Chapters 6–8.

The intrinsic heart rate is determined via blockade of both arms of the autonomic nervous system. When an animal is at rest, the PSNS is likely dominant, as the resting heart rate is lower than the intrinsic heart rate. Patients with heart failure often have higher resting heart rates and less heart rate variability, suggesting that the SNS is likely dominant over the PSNS at rest. Sympathetic stimulation of cardiac muscle (via endogenous NE and certain pharmacological agents) can markedly increase the force of contraction, irrespective of end-diastolic muscle length. A change in contractile strength that is independent of muscle length is referred to as a change in contractility or inotropy. In the presence of inotropic stimulation by the sympathetic system, cardiac output at each level of ventricular filling is enhanced over the basal state (Figure 21.1). Conversely, parasympathetic nerves exert their primary influences

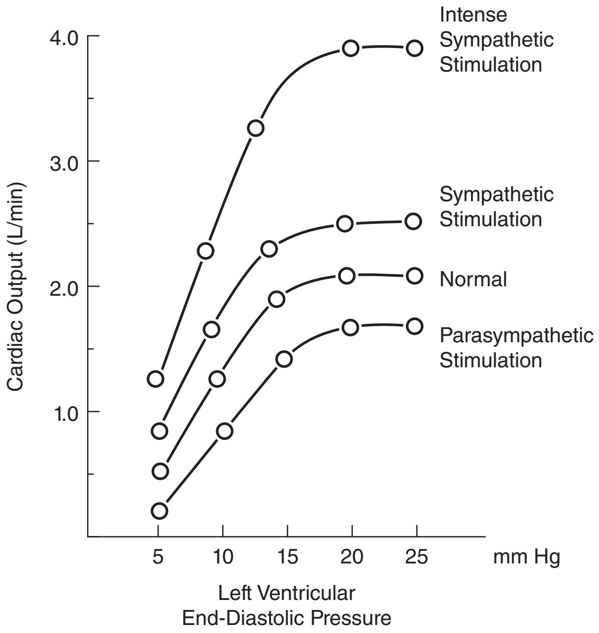

Figure 21.1 Frank–Starling law of the heart. As end-diastolic ventricular volume (preload) increases, the myofiber is stretched, enhancing the contractile state of the muscle; cardiac output is thus increased. The cardiac output curve can be influenced by different degrees of sympathetic and parasympathetic stimulation.

on cardiac output, not by changing the inotropic state, but by slowing heart rate and, with that, increasing ventricular filling time. Vagal discharge, however, when it produces bradycardia, decreases cardiac output at all levels of venous return and stretch on myocardial fibers (Figure 21.1). In contrast, sympathetic stimulation produces an increase in heart rate. Within physiological limits, cardiac output increases proportionately to the change in heart rate. Importantly, myocardial blood flow is decreased in rapid tachycardia, while myocardial oxygen needs are increased.

Myocardial oxygen demand (MVO_2) varies directly with three main factors: heart rate, myocardial wall tension, and inotropic state. Myocardial wall tension is directly related to ventricular radius (cardiac size) and intraventricular pressure and indirectly related to wall thickness (i.e., the law of Laplace). Primary determinants of ventricular wall tension are preload (i.e., end-diastolic volume and stretch) and afterload (determined by cardiac luminal size, wall thickness, and systemic blood pressure). By reducing pre- or afterload, certain drugs can elicit marked reduction in cardiac work (and MVO_2) without direct inotropic action on the heart muscle cell.

Cellular Concepts

The basic contractile unit of a heart muscle cell is the sarcomere, composed of actin (thin filament) and myosin (thick filament) proteins. A protein assembly unit, associated with the actin molecule, composed of tropomyosin and troponin, regulates activation of the filaments. Availability of ionized calcium (Ca^{++}) in the vicinity of troponin is the obligate modulator of the diastole–systole contraction cycle. Binding of Ca^{++} to a high-affinity subunit of the troponin molecule evokes the movement of tropomyosin from its diastolic blocking position on actin. Cross-linkages or “cross-bridges” are formed between projections of the myosin molecules and exposed sites on actin. As cross-bridges are formed, the thick and thin filaments slide over each other, and contraction occurs. Calcium delivery to the myofibrils is initiated by bioelectric events at the cell membrane, represented by the cardiac action potential.

Excitation–Contraction Coupling

L-type Ca^{++} channels are opened as the wave of depolarization travels down the T tubules, leading to the release of a small amount of Ca^{++}. This Ca^{++} triggers the activation of Ca^{++} release channels on the sarcoplasmic reticulum (SR) and causes the release of relatively large amounts of Ca^{++} into the cytosol (Opie, 2001; Fabiato and Fabiato, 1979).

Two separate pathways of movement of superficial Ca^{++} are believed to be involved (Langer, 1976, 1980; Parker and Adams, 1977). The primary electrogenic route is associated with the previously discussed triggered Ca^{++} release from the SR. An additional influx of Ca^{++} is linked with a Ca^{++}–Na^+ exchange across the sarcolemma. A schematic representation of excitation–contraction coupling in mammalian heart muscle is shown in Figure 21.2.

Relaxation

During repolarization, Ca^{++} is actively sequestered by the SR, which avidly binds and stores myoplasmic Ca^{++} with affinity greater than troponin. Relaxation occurs as Ca^{++} moves to the SR from troponin binding sites on the myofibrils, and the cytoplasmic Ca^{++} concentration decreases below the threshold required to trigger actin–myosin cross-bridge formation (Figure 21.2). Since this is an energy-requiring process, relaxation is somewhat a misnomer for the changes that occur during diastole.

Maintenance of Electrolyte Gradients

There is a net influx of Na^+ and Ca^{++} and efflux of K^+ with each action potential. Membrane-bound enzymes act as pumps to relocate ions and prevent their improper accumulation (Gadsby, 1984). Sodium–potassium–activated adenosine triphosphatase (Na^+,K^+-ATPase), localized in the cell membrane, propels Na^+ out of and K^+ into the cell, against their respective concentration gradients. Excess intracellular Ca^{++} is pumped out of the cell by systems localized in regions of the SR in close approximation

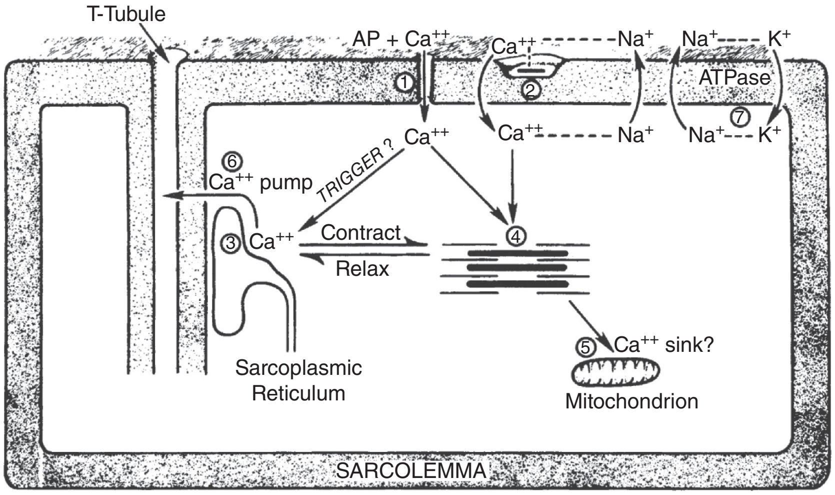

Figure 21.2 Schematic representation of cellular ion movements controlling excitation–contraction coupling in heart muscle. An action potential (AP) instigates the inward movement of Ca^{++} through slow Ca^{++} channels of the sarcolemma (1). Inward-moving calcium fills sarcoplasmic reticulum stores of the cation and also serves as a trigger to release additional Ca^{++} from storage sites of the sarcoplasmic reticulum (3). These Ca^{++} sources and that resulting from Na^+–Ca^{++} exchanges across the sarcolemma (2) activate the contractile proteins (4). Relaxation occurs as calcium is sequestered at storage sites of sarcoplasmic reticulum (3). Mitochondrion (5). Ca^{++} is pumped out of the cell (6). Altered sodium pump activity (7) may also affect sodium concentrations available from Na^+–Ca^{++} exchange. Source: Parker and Adams, 1977.

to the sarcolemma (Figure 21.2). A sarcolemmal Ca^{++}-ATPase also contributes to extrusion of Ca^{++}.

Positive Inotropes and Inodilators

Digitalis and Related Cardiac Glycosides

Digitalis and several closely allied chemicals are derived from the purple foxglove plant (*Digitalis purpurea*), other related species of the figwort family, and some plant species unrelated to digitalis.

Chemistry and Sources

Chemical and structure–activity relationships of the digitalis glycosides are quite complex, but several basic similarities are retained in the different compounds. The nomenclature is based on botanical origins rather than chemical structure. Digitalis is the dried leaf of the purple foxglove plant. Digitoxin, digoxin, and gitoxin also can be extracted from the leaf of a related plant, *D. lanata,* the woolly foxglove. Strophanthidin and ouabain are glycosides contained in the seeds of *Strophanthus* sp. Digitoxin and ouabain have been removed from the commercial market and only digoxin will be discussed here. Because of considerable pharmacological similarities between the different glycosides, the collective term *digitalis* has been used to designate the entire group of drugs, including digoxin. Often, *digitalis* and *digoxin* are used interchangeably by cardiologists. The term *glycoside* in general refers to a compound linked by an oxygen atom to a sugar molecule(s). The basic steroid-type nucleus is a cyclopentanoperhydrophenanthrene, to which is attached an unsaturated lactone ring at carbon atom 17 (C-17). The sugar molecules usually are attached at C-3; they influence water solubility, cell penetrability, duration of action, and other pharmacokinetic characteristics. The cardioactivity of the molecule resides principally in the aglycone moiety, but the positive myocardial actions of these entities are somewhat less potent and of lesser duration than the parent glycoside.

Cardiovascular Effects

Improved myocardial contractility was once considered to be the most important trait of the glycosides and, indeed, is the primary action on which the hemodynamic benefits depend. Today however, neuroendocrine (neurohormonal) effects, including reduced SNS activity and heart rate control, are believed to be of most important in treating heart failure.

Myocardial Contractility

The ability of cardiac glycosides to increase contractility has been demonstrated in a multitude of experimental preparations with results that validate a direct effect on contractile strength, independent of changes in resting fiber length, heart rate, or afterload. The positive inotropic action of cardiac glycosides is most pronounced in the hypodynamic or failing heart, though it is less than with other inotropic agents, such as dobutamine. Digitalis was shown in one study to provide a 24% increase in cardiac index versus 34% with dobutamine CRI (continuous rate infusion; ~3 μg/kg/min), meaning that the latter has a 42% greater inotropic effect than digoxin (Vatner et al., 1974).

Cellular Mechanisms of Inotropic Action

One of digitalis' proposed actions in congestive failure is a positive cardiac inotropic effect, but significance of this effect has diminished after examining results of several investigations. The second restorative action is neurohormonal normalization, thought by many to be the more important of known and postulated mechanisms of digitalis' clinical benefits (see Section Neuroendocrine Effects) (Ferguson, 1989).

Inhibition of Na$^+$,K$^+$-ATPase: The Mg^{++}-dependent Na$^+$,K$^+$-ATPase of the cell membrane supplies energy for the active pumping of Na$^+$ outward and K$^+$ inward against their large concentration gradients (Figure 21.2). The Na$^+$,K$^+$-ATPase is believed to be the cellular receptor for digitalis glycosides (Schwartz, 1977; Akera and Ng, 1991; Schatzmann, 1953). Inhibition of Na$^+$,K$^+$-ATPase by digitalis results in progressive reduction of $(K^+)_i$ as the ability of the pump to transport K$^+$ inward and Na$^+$ outward progressively fails (Fozzard and Sheets, 1985; Katz et al., 1985). A decrease in $(K^+)_i$ and/or an increase in $(K^+)_o$ reduces resting membrane potential to a less negative value, which can lead to increased automaticity and eventually impaired conduction and excitability. Inhibition of ATPase and resulting depletion of $(K^+)_i$ are responsible for the *arrhythmogenic properties* of digitalis.

The *inotropic effect* involves activation of a Na$^+$–Ca^{++} exchange mechanism through accumulation of $(Na^+)_i$. Baker et al. (1969) demonstrated with the giant squid axon that an increase in $(Na^+)_i$ enhanced the uptake of Ca^{++} by a Na$^+$–Ca^{++} exchange process. This mechanism seems to be operative in other excitable tissues and has been evoked as the link between inhibition of Na$^+$,K$^+$-ATPase and digitalis inotropy in the heart (Langer, 1977). The sequence of events can be visualized to include the following progression: digitalis interacts with and inhibits cell membrane Na$^+$,K$^+$-ATPase, outward pumping of Na$^+$ is slowed, $(Na^+)_i$ accumulates, increased $(Na^+)_i$ augments transmembrane exchange of intracellular Na$^+$ for extracellular Ca^{++}, $(Ca^{++})_i$ is increased, and Ca^{++} delivery to the contractile proteins is increased; thus the positive inotropic effect is gained. Dominance of Na$^+$–K$^+$ exchange and augmentation of Na$^+$–Ca^{++} exchange, with digitalis' inhibition of ATPase is demonstrated in Figure 21.3.

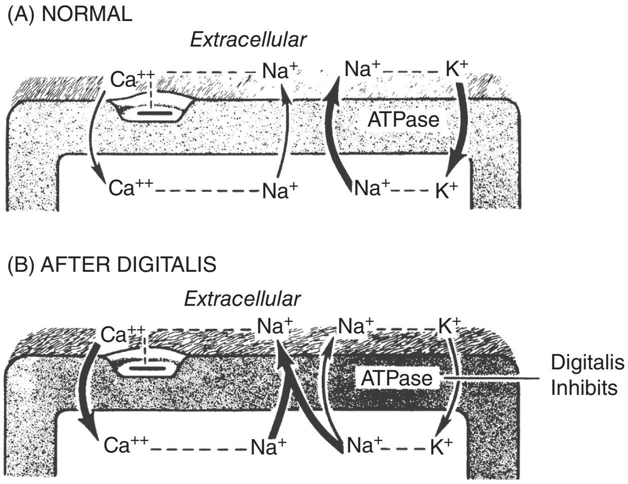

Figure 21.3 Schematic representation of a proposed mechanism for the positive inotropic action of cardiac glycosides. Inhibition of Na$^+$,K$^+$–ATPase (sodium pump) by digitalis results in increased intracellular concentrations of sodium available for exchange with calcium. Heavy arrows designate the dominant pathway of ion exchange during normal conditions (A) and after inhibition by digitalis of Na$^+$,K$^+$–ATPase (B). Adapted from Langer, 1976; Source: Parker and Adams, 1977.

Cardiac output

Digitalis glycosides increase contractility in both the normal and failing myocardium. However, the change in cardiac output is influenced by the functional status of the cardiovascular system.

Normal heart: Output of the normal heart increases minimally and may even decrease slightly after treatment with digitalis (Braunwald, 1985). Total peripheral resistance is increased by digitalis in the normal subject as a result of a centrally mediated increase in sympathetic vasomotor tone and direct vasoconstrictor effect. Impedance of the arterial circuit to ventricular ejection (afterload) is thereby increased, which attenuates the expected increase in cardiac output produced by the positive inotropic effect.

Failing heart: The work capacity of the failing ventricle at any given end-diastolic volume or pressure is inadequate to generate a normal stroke volume (Figure 21.4). The ejection fraction is diminished accordingly, which increases residual blood in the ventricle after systole (Moalic et al., 1993). If diastolic filling continues at a near normal rate, the ventricle will dilate to accommodate increased end-diastolic volume. With the administration of digitalis, the above processes are reversed. Digitalis-increased myocardial contractility augments work capacity of the ventricle, at any given end-diastolic filling pressure, as illustrated in Figure 21.4, where ventricular function curves derived in the prefailure state (normal) are compared with curves derived from congestive failure patients prior to and after digitalis therapy. Digitalis shifts the complete ventricular function curve upward in the direction of improved contractility (Mason, 1973; Braunwald, 1985). Systolic emptying is now more complete (increased ejection fraction) and, therefore, residual ventricular volume is diminished. Cardiac output increases and the size of the heart is reduced.

Digitalis' augmentation of myocardial contractility and normalization of baroreceptor function favorably affect vasomotor tone, evoking peripheral vasodilation with diminished outflow impedance (afterload). Additionally, improved cardiac performance increases venous return to the heart, thereby increasing preload and further enhancing cardiac performance by the Frank–Starling mechanism. This sequence of events continues to dominate as peripheral perfusion and tissue oxygenation improve, and it compensates for the direct vasoconstrictor effect of digitalis. The increase in cardiac output persists as long as the state of myocardial compensation prevails.

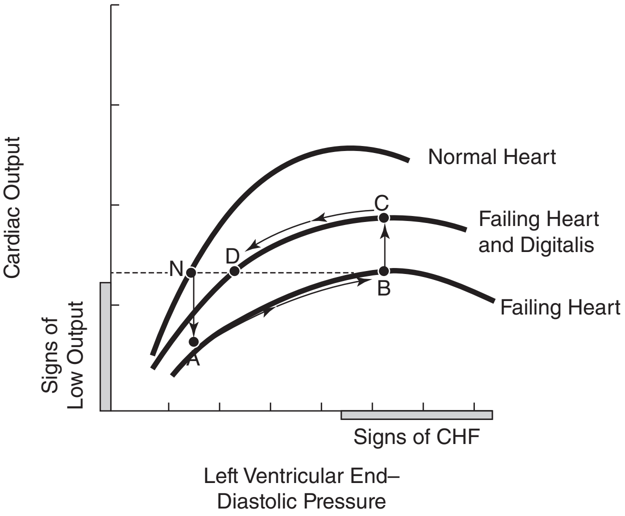

Figure 21.4 Diagrammatic representation of how changes in left ventricular filling influence cardiac output by the Frank–Starling mechanism in a normal heart and in a failing heart before and after digitalis. The points N to D represent in sequence: N–A, normal cardiac output falls to A because of initial contractile depression from congestive heart failure (CHF); A–B, shift to higher end-diastolic filling and thus higher cardiac output in accord with the Frank–Starling law; B–C, increase in contractility after digitalization; C–D, reduction in use of Frank–Starling compensation, which digitalis allows. N, B, and D: identical cardiac output on the vertical axis but achieved at different end-diastolic filling pressure on the horizontal axis. Levels of cardiac output and end-diastolic filling associated with signs of low output (e.g., fatigue) or CHF (e.g., dyspnea, edema) are represented by the dotted areas. Source: Adapted from Mason, 1973.

Cardiac Energy Metabolism

Digitalis increases oxygen consumption proportionately with increased contractile force in nonfailing cardiac muscle (Lee and Klaus, 1971); but patients with heart failure do not show an increase in the myocardial oxygen consumption because of the slowing of heart rate and the reversal of SNS-derived vasoconstriction.

These seemingly contradictory data can be reconciled by comparing the cardiodynamics of digitalis in normal and failing hearts. The heart with a normal ventricular volume responds to digitalis with increase in oxygen consumption commensurate with increase in contractility. Increased oxygen consumption is the direct result of increased contractility, in accordance with the concept that MVO_2 is influenced directly by the inotropic state, heart rate, and wall tension. Ventricular wall tension is directly proportional to ventricular pressure and radius (tension = (pressure × radius)/wall thickness; the Laplace relation). Tension will decrease if either pressure or radius is reduced. In the failing and dilated heart, reduction in cardiac size secondary to the inotropic action of digitalis therapy leads to a significant reduction in wall tension, which in turn leads to decreased MVO_2. The ultimate determinant of cardiac output is then a balance of the positive effect of increased preload on force of contraction and its negative effect on afterload, by reduction in cardiac chamber size (Laplace relation). Blood pressure normalization after cardiac glycoside therapy is secondary to cardiodynamic improvement in the congestive failure patient (Figure 21.4).

Neuroendocrine Effects

In heart failure patients, a lowering of heart rate accompanies the positive inotropic effect. This is apparently the result of a *neuroendocrine effect* and has been recognized as perhaps more important than the positive inotropic effects at therapeutic dosages. It also appears that the neuroendocrine effects are independent from the positive inotropic action and occur at lower serum digoxin levels (<1 ng/ml) (Ferguson, 1989). Neuroendocrine effects are achieved through digitalis' increase (normalization) in the baroreceptor reflex sensitivity that has been lost, presumably because of high levels of circulating aldosterone, during heart failure (Weber, 2001). Digitalis restores baroreceptor sensitivity and thereby decreases sympathetic tone in patients with heart failure (Quest and Gillis, 1971; McRitchie and Vatner, 1976; Zucker et al., 1980; Ferrari et al., 1981). The neuroendocrine effects also are attributed to direct pharmacological vagal stimulation (parasympathomimetic effect) (Thames et al., 1982). The neuroendocrine effects are responsible for a decrease in sinus rate, afterload, and speed of atrioventricular (AV) impulse conduction, thereby reducing cardiac work and MVO_2. Ahmed and Pitt have shown that the positive effects of digoxin are maintained and survival benefits enhanced at serum digoxin concentrations of 0.7–0.9 ng/ml, *but not higher* (Ahmed et al., 2006a,b; Ahmed et al., 2008), for both systolic and diastolic failure.

Excitability and Automaticity

As described earlier the increased excitability of digoxin on the heart is caused by ion fluxes and changes in K^+ conductance. Pacemaker cells are characterized by phase 4 spontaneous depolarization (normal automaticity), which moves diastolic potential to the threshold required for activation of phase 0, causing spontaneous depolarization (see Chapter 22). Therapeutic doses of cardiac glycosides increase vagal tone and decrease sympathetic tone, decreasing the slope of spontaneous diastolic depolarization of the sinoatrial pacemaker. This reduces the firing frequency of the sinoatrial node, and hence heart rate. After pretreatment with atropine, or with relatively high doses of digitalis, the nonvagal effects dominate, and an increase in automaticity is observed; this response is prevalent in the specialized conducting systems of atria and, especially, the ventricles. A typical transmembrane potential recording of a subsidiary pacemaker cell prior to and after digitalis is shown in Figure 21.5. This increased automaticity evoked by cardiac glycosides is due to an accelerated rate of spontaneous

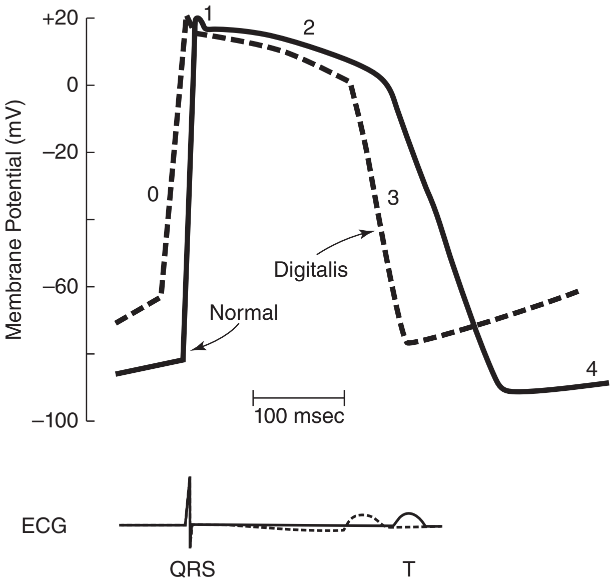

Figure 21.5 Electrophysiological effects of digitalis on transmembrane potential of a subsidiary pacemaker cell. Digitalis (i) decreases (less negative) the maximal diastolic potential, (ii) decreases the maximal rate of depolarization of phase 0, V_{max}, and (iii) enhances automaticity by increasing the slope of phase 4 spontaneous depolarization. (i) and (ii) lead to decreased conduction velocity and, in conjunction with (iii), can lead to arrhythmias of both impulse formation and impulse conduction. Source: Adapted from Mason et al., 1971.

diastolic depolarization. The normally latent pacemaker activities of cells within the ventricular conducting system are thereby magnified, leading to ectopic ventricular beats as an important early sign of digitalis toxicity. In contrast, muscle fibers in atria and ventricles can be depolarized to the point of inexcitability, without demonstrating spontaneous impulse generation. If excitability of ventricular muscle falls sufficiently, concomitant with increased frequency of ectopic impulses from specialized conduction fibers, the tendency for ventricular fibrillation is promoted.

The clinical significance of the “delayed afterdepolarizations” sometimes seen with digitalis toxicity is not completely resolved. These oscillations of the transmembrane potential initially are subthreshold and appear spontaneously during diastole after a usual action potential. These afterdepolarizations can, however, reach threshold as toxicity worsens, with the resulting extrasystoles contributing to ectopic arrhythmias associated with digitalis intoxication.

Impulse Conduction and Refractory Periods

The dominant effect of digitalis on impulse conduction is to slow conduction velocity by both vagal and nonvagal mechanisms. This response is particularly prevalent in the AV node and contributes importantly to the beneficial effects of digitalis in controlling ventricular rate during atrial fibrillation and flutter. Antiarrhythmic agents are discussed further in Chapter 22 of this book.

Digitalis Effects During Atrial Fibrillation and Flutter

During atrial fibrillation, the ventricular rate is rapid and dysrhythmic, as a result of rapid transmission of impulses through the AV node. This contributes further to cardiac dysfunction by promoting incomplete ventricular filling and ejection. Because digitalis prolongs the refractory period and delays impulse conduction through the AV node, fewer impulses will effectively reach the ventricle. Thus ventricular response rate is reduced to a slower, more physiological level (Ferguson et al., 1989).

Similar benefits are gained during atrial flutter. Digitalis can slow this rhythm or convert it to atrial fibrillation. Ventricular rate is still decreased, however, through prolonged AV refractoriness and slowed impulse conduction. Conversion of atrial flutter to fibrillation by digitalis is viewed optimistically because ventricular rate is controlled more easily during fibrillation than during flutter. It has been shown that the combination of digoxin and the Ca^{++} channel blocker, diltiazem (which also slows conduction through the AV node), is more effective at slowing the ventricular response to atrial fibrillation than is either drug alone (Gelzer et al., 2009).

Effects on the Electrocardiogram

The multiplicity of electrophysiological effects of cardiac glycosides on myocardial tissues can be expressed as equally complex changes in the electrocardiogram (ECG). Most conduction disturbances and dysrhythmias can be produced in normal individuals by administration of cardiac glycosides.

Congestive failure patients with sinus tachycardia or other supraventricular tachyarrhythmias usually demonstrate return toward more normal ECG patterns after digitalization. Rapid ventricular rates associated with atrial fibrillation or flutter are typically, but often inadequately, reduced by digitalis. Prolonged PR intervals, reflecting delayed AV conduction, are relatively common ECG features of digitalized dogs. Conversely, a lengthened PR interval is not necessarily a prerequisite for the therapeutic response.

Kidneys and Diuresis

After digitalization, reflex vasoconstriction decreases as cardiac output and hemodynamics are improved. Renal blood flow and glomerular filtration rate increase and stimuli for increased release of aldosterone are diminished. A fall in aldosterone secretion can be measured after digitalization in the dog with congestive failure (Figure 21.5). Diuresis results as salt and water retention by the kidneys is decreased. Diuresis, with lowering of capillary hydrostatic pressure, moves interstitial fluid back into the vascular space, providing relief from edema. Diuresis is not a prominent feature of digitalis therapy if edema does not accompany the congestive failure syndrome. Similarly, digitalis does not evoke diuresis if edema is not cardiogenic. Thus the diuretic response to digitalis is secondary to circulatory improvement and is not from a direct effect on the kidney, and is virtually never adequate without concurrent loop diuretic therapy (Robinson, 1972).

Pharmacokinetics

Dog: The absorption of digoxin after oral administration of an elixir usually is uniform, up to 75–90%, with peak serum concentrations attained in 45–60 minutes (Krasula et al., 1976). With tablets, the peak serum concentration is less, and occurs somewhat later (90 minutes). After IV administration, the maximal positive inotropic responses to digoxin were obtained within 60 minutes after injection (Hamlin et al., 1971). Breznock (1973, 1975) reported that the plasma half-life value for digoxin was 38.9 and 55.9 hours in different studies. Others report approximate digoxin half-lives varying from 24 to 31 hours, with a median of 30 hours for six studies (Barr et al., 1972; Doherty, 1973; Breznock, 1973, 1975; Hahn, 1977; DeRick et al., 1978). The importance of interpatient variability is exemplified in a study that found the half-life for digoxin in dogs at steady state varied from 14.4 to 46.5 hours (DeRick et al., 1978). These variables strengthen the need for adoption of individual dosage regimens, depending on the patient's response and, especially, evaluation of the serum digoxin concentration (SDC).

Digoxin is 25% protein bound (Breznock, 1973) and urinary excretion seems to be the most important route of elimination. Digitalis glycosides and their biotransformation products can follow an enterohepatic cycle, in which compounds are excreted by the liver into bile and some parent glycoside and metabolites are subsequently reabsorbed. See Section Digitalis in Cats.

Horse: The pharmacokinetics in horses have been studied because digoxin is occasionally considered for congestive heart failure and supraventricular arrhythmias in these animals (Sweeney et al., 1993). After oral administration of 44 μg/kg, the oral absorption was approximately 23%, with a peak concentration of 2.2 ng/ml (Brumbaugh et al., 1983). The half-life was approximately 17 hours based on mean serum concentrations. The authors presented oral doses needed to attain predicted steady-state serum concentrations that ranged from 28 μg/kg to 64 μg/kg loading dose, followed by 11–25 μg/kg maintenance dose every 12 hours. The specific dose depends on the therapeutic target concentrations cited in their paper (Brumbaugh et al., 1983).

Digitalis Toxicity

Plasma concentrations: In humans and dogs, therapeutic and toxic serum drug concentrations (SDCs) are in the range of 0.8–1.6 ng/ml and greater than 2.4 ng/ml, respectively (Moe and Farah, 1975). In dogs, concentrations from 0.8 to 2.4 ng/ml have been considered to be therapeutic, whereas SDC greater than 2.5–3 ng/ml are associated with increased probability of toxicosis. Nontoxic digoxin plasma concentrations have been determined for horses (0.5–2 ng/ml; Button et al., 1980); for cats (≤2.3 ng/ml; Erichsen et al., 1980); and for dogs (≤2.5 ng/ml; DeRick et al., 1978). Toxicity signs are generally mild or absent when serum digoxin concentrations are less than 2.5 ng/ml; moderate with SDC of 2.5–6 ng/ml; and severe, even fatal, when SDC exceeds 6 ng/ml (Fillmore and Detweiler, 1973; Teske et al., 1976).

Today, with the knowledge that neurohormonal and clinical benefits occur at much lower serum concentrations than needed for inotropic benefit (Ahmed et al., 2006a, 2006b; Ahmed et al., 2008) digoxin toxicity is much less a problem. In nonemergent situations, the authors advocate an initial low dosage, relying upon *other drugs discussed in this chapter* to control immediate signs. This is followed by uptitration of digoxin dosage over 2–3 weeks, using serum concentrations taken 8 hours posttreatment with a target SDC of 0.8–1.2 ng/ml. If kidney function declines, dose adjustments may be necessary to prevent accumulation of high concentrations of digoxin.

Clinical signs: Digitalis intoxication is characterized by clinical signs varying from mild gastrointestinal upset to neurological signs and death (Detweiler, 1977; Tilley, 1979). Relative inappetance, depression, and loose stools are common side effects, which are often self-limiting. Vomiting, however, is viewed more seriously, especially if protracted diarrhea is an accompaniment and these individuals should be examined for additional evidence of toxicity. Lethal outcomes are most often due to cardiac arrhythmias. The authors emphasize that the presence of any sign that can be seen with toxicosis should be considered to indicate toxicosis and action taken. This ideally triggers an office visit, SDC measurement, and serum biochemistry to evaluate kidney values. An ECG should be examined in dogs suspected of digoxin toxicity. The effects of digoxin on the ECG were described in Section Effects on the Electrocardiogram. Occurrence of ECG abnormalities necessitates: complete withdrawal of digitalis therapy; measurement of SDC; possibly other medical intervention; and reduction in dosage when reinstituted.

Electrolyte Involvement: Low K^+ concentration potentiates digitalis arrhythmogenicity and lessens efficacy of its treatment, whereas excess K^+ antagonizes arrhythmogenic activity. The antiarrhythmic activity of K^+ in digitalis intoxication is probably related to inhibition by the cation of glycoside binding to the Na^+,K^+-ATPase.

Treatment: Discontinuing digoxin administration is the first step to treat toxicity. Serum drug concentrations and ECG should be evaluated. Other drugs can be considered to replace digoxin in treatment (other drugs discussed in this chapter).

Digoxin immune FAB (Digibind®): This is an ovine source of antidigoxin antibodies. This treatment has been used in animals but is expensive. One vial contains 38 mg digoxin immune FAB and will neutralize 500 μg of digoxin. Animals will improve quickly after administration. After therapy with Digibind, free digoxin levels decreased whereas bound digoxin (to FAB) levels will rise.

Antiarrhythmic therapy: *Antiarrhythmic therapy for digitalis intoxication is not specific and treatment of specific arrhythmias is handled elsewhere* (see Chapter 22). Atropine may be helpful in cases with severe sinus bradycardia or AV block. In the presence of AV block, therapy with beta-blockers and calcium channel blockers should be avoided. Quinidine should be avoided as it may actually cause an increase in plasma concentrations of digoxin, probably by blocking the efflux transporter, p-glycoprotein (Discussed in Chapter 22).

Therapeutic Indications for Digitalis

Congestive heart failure: Controversy exists relative to the actual survival benefits of digitalis glycosides in the long-term therapeutic management of cardiac disease in animal and human patients (Hamlin et al., 1973; Patterson et al., 1973; Braunwald, 1985; Kittleson et al., 1985a). In man, no study has ever shown *overall* improvement in survival with digitalis therapy. However, improvement in quality of life and reduction in hospitalization have been demonstrated (Packer et al., 1993;Digitalis Investigation Group, 1997;Whitbeck et al., 2013). With low serum digoxin levels (0.5–0.9 ng/ml) there was a benefit, which was lost at higher serum levels (Ahmed et al., 2006a,b; Ahmed et al., 2008).

Cardiac glycosides are theoretically indicated in *systolic* heart failure of any etiology. New inodilator drugs (pimobendan discussed in Section Inodilators: Pimobendan) have largely taken the place of digitalis in managing heart failure in animals.

Atrial arrhythmias: Many specialists use digoxin (often with diltiazem) to control the heart rate in atrial fibrillation, when there is a rapid ventricular response (Gelzeret al., 2009).This therapeutic choice is made easier if heart failure is also present, especially with evidence of poor systolic function (e.g., dilated cardiomyopathy). However, digoxin does not produce conversion to a sinus rhythm, but reduces ventricular rate by slowing AV conduction (Meijler, 1985).

Precautions: The authors do not initiate digoxin treatment unless rate control is needed and/or if inotropic support is needed and finances precluded the use of other positive inotropic agents. Digitalis therapy is not used in the presence of heart block or ventricular tachycardia.

Digoxin should not be used to reduce heart rate when sinus tachycardia is present without evidence of heart failure. Tachycardia, associated with other conditions, such as fever, thyrotoxicosis, pain, anxiety, or even cardiac conditions, such as pericardial effusion with tamponade or with hypertrophic cardiomyopathy (HCM), is not amenable to digitalis therapy.

Clinical Practice

Generally, digoxin is initiated at the low end of the dose range listed below, then increased gradually if necessary to achieve the desired therapeutic outcome. If toxicity is observed, monitoring and assessment – as described in this chapter – should be used to adjust the dosage or make a determination about discontinuing digoxin administration. A listing of average digitalis glycoside dosages is provided in formularies for dogs and cats (Tables 21.1 and 21.2). The dosage regimens published for dogs have used both a mg/kg and mg/m^2 dosing schedule, the latter based on body surface area. There is some evidence that dosing on a body surface area basis may be safer than mg/kg dosing (Kittleson, 1983).

Parenteral schedules: IV administration increases the likelihood for toxicity, including life-threatening arrhythmias, and this route is rarely used for administration. Digoxin is sufficiently absorbed by the oral route that IV administration is not ordinarily necessary. Intravenous dosing regimens are provided in previous editions of this book.

Digitalis in Cats

There are less data on administration of digoxin to cats compared to dogs. There are no studies of survival or quality of life (Atkins et al., 1988, 1989, 1990); however, there are evaluated clinically relevant aspects of digitalis therapy in cats.

The effect of concurrent therapies on digoxin pharmacokinetics was measured and results presented in Table 21.3. The study showed that other drugs can affect digoxin through unidentified mechanisms. The authors also compared results between the 10 and 20-day evaluations, indicating that at steady state there is no effect

Table 21.1 Medical management of factors contributing to signs of systolic heart failure in dogs. Source: Adapted from Atkins CE. Atrioventricular valvular insufficiency. In Allen DG (ed): *Small Animal Medicine,* Lippincott, 1992.

Factor	Strategy	Agent and dosage
Fluid retention/ excessive preload	Salt restriction	Senior diet, renal diet or, late in course, heart (heavily salt-restricted) diet
	Diuresis	Furosemide 1–4 mg/kg SID–TID, IV, IM, SC, or PO or CRI at 0.66 mg/kg/min
		Torsemide 0.2 mg/kg PO SID–TID
		Hydrochlorothiazide or aldactazide 2–4 mg/kg QID–BID PO
		Chlorthiazide 20–40 mg/kg BID PO
		Spironolactone 2.0 mg/kg SID PO
	Venodilation	Triamterene 2–4 mg/kg/day PO
		Nitroglycerin 2% ointment 0.5 cm per 5kg TID topically for 1st 24 hours
		Captopril 0.5–2 mg/kg TID PO
		Enalapril 0.5 mg/kg SID–BID PO
		Benazepril 0.25–0.5 mg/kg SID PO
		Prazosin 1 mg TID if <15 kg; 2 mg TID if >15 kg
		Sodium nitroprusside 1–5 µg/kg/min IV
Neurohormonal aberration	Blunt RAAS	Captopril 0.5–2 mg/kg TID PO
		Enalapril 0.5–1 mg/kg SID–BID PO
		Benazepril 0.25–0.5 mg/kg SID PO
		Spironolactone 2.0 mg/kg/day PO
		Angiotensin II receptor blocker (e.g., losartan) dosage TBD
	Blunt SNS	Digoxin 0.005–0.01 mg/kg or 0.22 mg/m^2 body surface BID PO for maintenance
		Propranolol 5–40 mg TID PO
		Atenolol 0.25–1 mg/kg PO[b]
		Carvedilol 0.1–0.2 mg/kg SID PO, increasing to 0.5–1mg/kg BID over 6 weeks
Increased afterload	Arterial vasodilation	Hydralazine 1–3 mg/kg BID PO
		Captopril 0.5–2 mg/kg TID PO
		Enalapril 0.5 mg/kg SID–BID PO
		Benazepril 0.25–0.5 mg/kg SID PO
		Prazosin 1 mg TID PO if <15 kg; 2 mg TID if >15 kg PO
		Sodium nitroprusside 1–5 µg/kg/min IV
		Diltiazem 0.1–0.2 mg/kg IV slowly; 0.5–1.5 mg/kg TID PO
		Amlodipine 0.1–0.2 mg/kg SID–BID PO
		Sildenafil 0.5–1 mg/kg SID–BID PO
Diminished contractility[a]	Positive inotropic support	Digoxin 0.005–0.01 mg/kg or 0.22 mg/m^2 body surface BID PO for maintenance
		Rapid oral: 0.01 mg/kg BID to 0.02 mg/kg TID for 1 day, then to maintenance
		Rapid IV: 001–0.02 mg/kg given one half IV immediately and one-fourth IV at 30 to 60-min intervals PRN
		Dobutamine 1.5–20 µg/kg/min IV for <72 hours
		Dopamine 2–10 µg/kg/min IV for <72 hours
		Amrinone 1–3 mg/kg IV followed by 10–100 µg/kg/min
		Pimobendan 0.25 mg/kg BID PO

[a] In most instances of mitral insufficiency, positive inotropic support is unnecessary.

[b] Calcium channel (verapamil and diltiazem) and beta-blockers (propranolol, esmolol, atenolol) should be used with caution in patients in heart failure.

SID, once daily; BID, twice daily; TID, three times daily; QID, four times daily; IM, intramuscularly; IV, intravenously; SC, subcutaneously; PO, per os; PRN, as needed; RAAS, renin–angiotensin–aldosterone system; SNS, sympathetic nervous systems.

of duration of therapy on pharmacokinetics in normal cats (Atkins et al., 1988). Pharmacokinetics were also examined in cats with compensated dilated cardiomyopathy (DCM) compared with six clinically normal cats (Atkins et al., 1989) at a dosage of 0.01 mg/kg, q 48 h for 10 days. There were no differences between control and heart failure cats. Other studies have shown hemodynamic improvement in cats with heart failure due to DCM (Atkins et al., 1990).

One can conclude from these studies, and others, that digoxin is effective in cats with DCM, when given q 48 h, that concurrent treatment alters pharmacokinetics, predisposing to toxicity, but that the heart failure state per se and prolonged therapy does not further affect these parameters. The recommended dosage for cats in heart failure is 0.007 mg/kg q 48 h and SDC should be determined at steady state, 8 hours posttreatment, with a goal of 0.8–1.2 ng/ml.

Table 21.2 Feline formulary

Drug	Trade Name[a]	Formulation(s)[b]	Dosage	Use
Amlodipine	Norvasc	1.25 mg tablets	0.625 mg PO QD–BID	Antihypertensive
Diltiazem	Cardizem	30 mg tablets	7.5 mg PO TID	Lusitrope, Vasodilator, Negative chronotrope
Diltiazem - LA				
	Dilacor XR	180, 240 mg capsule	30 mg PO BID	*same*
	Cardizem CD	180, 240 mg capsule	45 mg PO QD	*same*
Enalapril	Enacard (Vasotec)	1, 2.5, 5 mg tablet	0.5 mg/kg PO QD	ACEI (CHF, Hypertension)
Benazepril	Lotensin (Foretkor)	5, 10 mg tablet	0.25–0.5 mg/kg PO QD–BID	*same*
Atenolol	Tenormin	25 mg tablet	6.25–12.5 mg PO QD	Negative chronotrope, Antiarrhythmic, Lusitrope, Antihypertensive
Esmolol	Brevibloc	10, 250 mg/ml injectable	50–500 (100 usually) µg/kg IV	*same*
Sotalol	Betapace	80 mg tablet	2 mg/kg PO BID	Antiarrhythmic
Procainamide	Pronestyl, Procan SR	250 mg tablet100 mg/ml injectable	2–5 mg/kg PO BID–TID	Antiarrhythmic
Furosemide	Lasix	12.5 mg tablet 50 mg/ml injectable	1–4 mg/kg PO BID–q 48 h; 0.5–2 mg/kg SQ, IM, IV PRN	Diuretic
Nitroglycerin	Nitrol, Nitro-Bid	2% ointment	2–5 cm topically TID for 24 h	Venodilator (CHF)
Warfarin	Coumadin	1, 2, 2.5, 4 mg tablet	0.1–0.2 mg QD	Anticoagulant
Heparin		Multiple	250–300 U/kg SQ TID	Anticoagulant
LMW Heparin	Fragmin	2500 U/0.2 ml	100 U/kg SQ QD	Anticoagulant
Aspirin	Plavix	81 mg	40–80 mg q 72 h	Anticoagulant
Clopidogrel		75 mg	17.5 mg daily	Anticoagulant
Digoxin	Lanoxin	0.05 mg/ml elixir 0.125 mg tablet	0.007 mg/kg PO q 48 h (check serum [digoxin])	Positive inotrope, Negative chronotrope (CHF, SVT)
Taurine		250 mg tablet	250 mg PO QD	Taurine deficiency
Cyproheptadine	Periactin	4 mg tablet	2 mg BID	Prevent SAE vasoconstriction (?)

[a] Selected name brands, some available as generic.

[b] Most appropriate formulations for cats; other sizes available for many drugs.

BID, twice daily; TID, three times daily; IM, intramuscularly; IV, intravenously; SQ, subcutaneously; PO, per os; PRN, as needed.

*Significantly different from that value within the same group (P <0.05).

ASA, aspirin; DXN, digoxin; FRS, furosemide.

Preparations

Digoxin, USP – cardiotonic glycoside from *D. lanata.*

Digoxin Injection, USP – digoxin in 10% alcohol; injections, 0.5 mg/2 ml.

Digoxin Tablets, USP – tablets, 0.25 and 0.5 mg.

Digoxin Solution – digoxin, 0.05 mg/ml in oral solution.

Sympathomimetic Agents: Dobutamine and Dopamine

Sympathomimetic drugs, such as dobutamine and dopamine, can be used to support cardiac function and blood pressure acutely. Veterinary cardiologists have most often employed dobutamine for the emergency management of heart failure in dogs; there is less support for administration of dopamine.

Dobutamine

This agent, a synthetic sympathomimetic, produces improvement in cardiac performance by complexing primarily with myocardial β_1 receptors, which, through second messengers, increase intracellular calcium and, thereby, myocardial contractility. There is both agonist and antagonist effects on α receptors, the clinical effects of which are uncertain. Dobutamine is unique as a SNS-agonist as it has relatively little effect on heart rate, is minimally proarrhythmic, and has a very short half-life (1–2 minutes). The short half-life allows for quick adjustment of dose rates and if the infusion is discontinued the effects quickly dissipate. The short half-life also requires that it be administered as a constant rate infusion (CRI). Additionally, it results in down-regulation of β_1 receptors 48–72 hours after its institution, rendering the drug ineffective after this time. Furthermore, there is concern that the positive dromotropic effect of dobutamine in dogs with atrial fibrillation, not receiving digitalis, may increase AV nodal conduction to a degree that a life-threatening ventricular response rate may result in ventricular fibrillation. There are no clinical trials involving dobutamine in natural canine heart disease, but anecdotal evidence that it may be helpful for the acute management of heart failure in hospitalized patients.

Dobutamine is beneficial for emergency management of DCM, without atrial fibrillation or other supraventricular tachycardia. It provides inotropic support without increasing heart rate and can be life-saving when there is profound myocardial systolic dysfunction. There is no evidence of benefit for treatment of long-standing mitral valve regurgitation.

Dopamine

Dopamine, unlike dobutamine, is not a synthetic catecholamine, occurring naturally and formed endogenously from L-Dopa. It has a significant first pass effect and very short half-life, dictating that it can only be administered IV with a CRI. It has two known receptor subtypes with which it interacts (DA_1 and DA_2). DA_1 subserves vasodilation in the renal, cerebral, mesenteric, and coronary vasculature. DA_2 stimulation inhibits norepinephrine release from the postsynaptic nerves and autonomic ganglia. However, dopamine also stimulates β_1- and $\alpha_{1,2}$-adrenoreceptors, with the expected positive inotropic, chronotropic, dromotropic, and vasoconstrictive effects.

With this wide spectrum of effects, it is not surprising that clinical effects vary with dosage. At a low dosage (0.5–1 μg/kg/min), dopamine stimulates DA_1 only, thereby lowering blood pressure, without other hemodynamic effects. At intermediate dosages, cardiac benefits are recognized, with variable effects on heart rate, a lack of reduction in pulmonary capillary wedge pressure, but positive effects on cardiac output and renal blood flow. At high doses, vasoconstriction may be observed with increased cardiac afterload. Dopamine does not dilate capacitance vascular beds, so is sometimes accompanied by venodilators (nitroglycerin or nitroprusside) or by dobutamine. Concerns at this dosage range include arrhythmias and tachycardia. High dosages (2–10 μg/kg/min in normal humans to >50 μg/kg/min in shock patients) produce, in addition to tachycardia and arrhythmia, elevation of blood pressure and systemic vascular resistance through α_1 and α_2-adrenoreceptor stimulation with resultant vasoconstriction (Horowitz et al., 1962; Sprung et al., 1984). This is desirable only in shock management and should be preceded by fluid therapy to correct deficits.

In veterinary medicine, dopamine has found its greatest utility in the management of hypotension during anesthesia and treating noncardiogenic shock. Sisson and Kittleson (1999) recommend a starting dosage of 2 μg/kg/min, with upward titration or retreat as the clinical situation dictates. The ultimate dosage typically ranges from 1 to 8 μg/kg/min, administered by CRI (in 5% D/W, using an infusion pump to avoid excessive volumes in heart failure patients). Although it has been used, at low doses, to stimulate DA receptors, dilate renal vessels, and treat acute kidney disease, it has not been shown to produce these benefits in animal studies.

Preparations: Supplied in 5-ml vials containing 40, 80, 160 mg/ml.

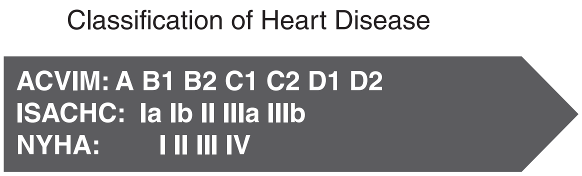
Inodilators: Pimobendan

Agents that have both vasodilatory and positive inotropic properties are classified as *inodilators* (Opie, 2001). Historically, short-term management of acute or decompensated heart failure characterized by systolic dysfunction benefited from a combination of dobutamine (positive inotrope) and nitroprusside (vasodilator). Inodilators combine these properties and agents such as pimobendan, which is available in an oral formulation, make chronic therapy a possibility. Levosimendan, another drug from this class having been investigated in animals, is not available for clinical use at this time.

Clinical Application

Pimobendan is a novel agent with properties useful in the clinical management of canine heart failure secondary to either DCM or myxomatous mitral valvular disease (MMVD). The efficacy of pimobendan in the treatment of heart failure, arising from DCM and MMVD, has been evaluated more thoroughly in dogs than have other cardioactive medications to date.

In dogs (English Cocker spaniels and Doberman Pinschers) with DCM and heart failure pimobendan was associated with a significant improvement in heart disease class (modified New York Heart Association [NYHA] functional class; overall, median NYHA 2 to NYHA 3), regardless of breed (Figure 21.6, Table 21.4). Other agents (furosemide, enalapril, and digoxin) also were allowed. However, only in the Doberman pinschers was there a significant survival benefit (Fuentes, 2004).



Classification of Heart Disease
ACVIM: A B1 B2 C1 C2 D1 D2
ISACHC: Ia Ib II IIIa IIIb
NYHA: I II III IV

Figure 21.6 The American College of Veterinary Internal Medicine Cardiac Disease Classification Scheme (ACVIM), the International Small Animal Cardiac Health Council (ISACHC) and New York Heart Association adaptation are categorically compared. See Table 21.4 for description. Source: Atkins et al. 2009.

Several high-quality studies have been performed on dogs with heart failure caused by cardiomyopathy or mitral valve disease (Lombard et al., 2006; O'Grady et al., 2008; Häggström et al., 2008; Summerfield et al., 2012). The results of these studies showed that pimobendan was effective, increased survival, and had a favorable safety profile. Some studies were multiinstitution, high-quality studies, for example, the QUEST trial (Häggström et al., 2008), the PROTECT study (Summerfield et al.,

Table 21.4 Functional classification schemes of cardiac disease in dogs

A. Modified New York Heart Association (NYHA) system (American)	
Class I	Includes patients with asymptomatic heart disease (typically murmur only)
Class II	Includes patients with signs of cardiac dysfunction only with strenuous exercise
Class III	Includes patients with heart disease that causes clinical signs with routine daily activities or mild exercise
Class IV	Includes patients with heart disease that causes severe clinical signs even at rest
B. International Small Cardiac Health Council (ISACHC) system	
Class I	The asymptomatic patient: Class IA: Signs of heart disease are present, but no signs of compensation (volume or pressure load ventricular hypertrophy) are evident Class IB: Signs of heart disease are present and signs of compensation (volume or pressure overload ventricular hypertrophy) are detected radiographically or echocardiographically
Class II	Mild-to- moderate heart failure; clinical signs of heart failure are evident at rest or with mild exercise, and adversely affect the quality of life
Class III	Advanced heart failure; clinical signs of advanced heart failure are immediately obvious: Class IIIA Home care is possible Class IIIB Hospitalization is recommended (cardiogenic shock, life-threatening pulmonary edema, or a large pleural effusion
C. American College of Veterinary Internal Medicine (ACVIM) scheme (adapted from American Heart Association and American College of Cardiology)	
Class A	Includes asymptomatic patients with no sign of cardiac disease but believed to be at risk because of genetic, environmental, or infectious causes
Class B1	Includes asymptomatic patients with heart disease, typically identified by the finding of a heart murmur, but without evidence of cardiac enlargement
Class B2	Includes asymptomatic patients with heart disease, typically identified by the finding of a heart murmur, which have evidence of hemodynamically significant valve regurgitation, evident by the finding of cardiac enlargement
Class C1	Includes patients with past or current clinical signs of heart failure, associated with structural heart disease, and requiring hospitalization
Class C2	Includes patients with past or current clinical signs of heart failure, associated with structural heart disease, which can be released from the hospital or which do not require hospitalization
Class D1	Includes patients in heart failure due to end-stage cardiac disease, which are refractory to standard therapy (requiring advanced or specialized treatment), requiring hospitalization
Class D2	Includes patients in heart failure due to end-stage cardiac disease, which are refractory to standard therapy (requiring advanced or specialized treatment) but that can be managed as outpatients

2012), and the EPIC trial. The EPIC study is a prospective trial, evaluating 360 client-owned dogs. EPIC, standing for evaluation of pimobendan in dogs with cardiomegaly caused by preclinical mitral valve disease, is a double-blind, randomized, placebo-controlled clinical trial, evaluating the effectiveness of pimobendan in the prevention of the onset of signs of congestive heart failure in dogs with cardiac enlargement secondary to preclinical myxomatous mitral valve disease. Preliminary results indicate that pimobendan is clearly beneficial and did not raise any concern over the administration of pimobendan.

In randomized prospective clinical trials, pimobendan has been proven to be safe and effective in heart failure secondary to both DCM (Doberman pinschers) and MMVD, as well as in asymptomatic DCM (Doberman pinschers) and MMVD. Pimobendan has been approved for use in dogs with congestive heart failure, beginning in 2000 in many countries around the world.

Pimobendan in cats: There are only a few studies to define the clinical use in cat. It produced improved survival in cats with nontaurine responsive dilated cardiomyopathy without adverse effects (Hambrook and Bennett, 2012). It improved survival and was well-tolerated in cats with congestive heart failure caused by cardiomyopathy (MacGregor et al., 2011; Reina-Doreste et al., 2014; Gordon et al., 2012). The pharmacokinetics have been performed in cats (Hanzlicek et al., 2012). The pharmacokinetic studies showed a rapid oral absorption and elimination half-life of 1.3 hours (mean). In other animals, pimobendan is metabolized (demethylated) to desmethylpimobendan, which is active and responsible for some of the cardiovascular effects. An observation from the feline pharmacokinetic study is that some cats may not be capable of metabolizing the parent drug to an active metabolite. The implications of the differences in metabolism among cats is undetermined until additional study results are available. The dosage is the same as in the dog, 0.25–0.3 mg/kg, q 12 h, oral. Administration of large oral tablets designed for dogs can be a challenge in cats.

Mechanism of Action

Inotropy: Pimobendan is a benzimidazole pyridazinone derivative that has effects as a positive inotrope and balanced arteriovenous dilator. In failing hearts it exerts its positive inotropic effects primarily through sensitization of the cardiac contractile apparatus to intracellular calcium. As a phosphodiesterase (PDE) III inhibitor, it can potentially increase intracellular calcium concentration and increase myocardial oxygen consumption. However, the cardiac PDE effects of pimobendan are reportedly minimal at pharmacological doses in dogs with heart disease, which is a major advantage relative to other inotropic PDE inhibitors such as milrinone. Pimobendan's calcium sensitization of the contractile apparatus is achieved by enhancement of the interaction between calcium and troponin C complex resulting in a positive inotropic effect that enhances systolic function, but does not increase myocardial oxygen consumption. The major advantage of pimobendan is its relative lack of the arrhythmogenic activity that is associated with positive inotropes whose sole mechanism of action is to increase myocardial intracellular calcium or cyclic AMP concentrations.

Vasodilation: Phosphodiesterase III and V are found in vascular smooth muscle. Inhibitors of PDE III, such as pimobendan, result in balanced vasodilation (combination of venous and arterial dilation) leading to a reduction of both cardiac preload and afterload, a cornerstone of therapy in heart failure. In addition, pimobendan may have some PDE V inhibitory effects. PDE V concentrations are relatively high in the vascular smooth muscle of pulmonary arteries; therefore, PDE V inhibition may ameliorate elevations in pulmonary artery pressure (pulmonary hypertension) that tend to parallel long-standing elevations in left atrial pressure, a clinically important complication of CVD. (Sildenafil is a specific PDE-V inhibitor, discussed in Section Phosphodiesterase V Inhibitors: Sildenafil.)

Cytokine modulation: The significance of alterations in proinflammatory cytokines, such as tumor necrosis factor-α and interleukins 1-b and 6, on the progression of heart failure has been documented in several forms of heart disease. Maladaptive alterations in these cytokine concentrations are associated with increased morbidity and mortality; pimobendan has demonstrated beneficial modulation of several such cytokines in models of heart failure (Iwasaki et al., 1999). Anecdotally, many clinicians feel that this results in attitude and appetite improvement beyond what is seen with control of heart failure alone.

Antiplatelet effects: In the dog, pimobendan has in vitro antithrombotic effects, but only at drug concentrations much higher than what can be clinically attained. Therefore, pimobendan's antiplatelet effects in the dog neither contributes to its therapeutic benefit nor confers risk of bleeding (Shipley et al., 2013).

Positive lusitropic effects: Via PDE III inhibition in cardiomyocytes, pimobendan increased intracellular cAMP, facilitating phosphorylation of receptors on the sarcoplasmic reticulum. Diastolic reuptake of calcium is thus enhanced, and the speed of relaxation increased, indicating a positive lusitropic property. Two small studies in the human and dog support this positive lusitropic property of pimobendan (Asanoi et al., 1994; Ishiki et al., 2000).

Pharmacokinetics

Pimobendan's absorption is rapid, with peak plasma levels achieved within an hour of oral administration. Thus, although pimobendan is an oral preparation, it can provide rapid, short-term support to dogs with emergent, acute-onset or decompensated heart failure. The elimination half-life in dogs is approximately 1 hour or less (Bell et al., 2015; Yata et al., 2016). Oral bioavailability is 60–65%, and as high as 70% (Bell et al., 2015), but because it is reduced in the presence of food, pimobendan should be administered at least 1 hour after feeding until steady state is reached. Pimobendan is water insoluble, highly protein bound (90%–95%), excreted into bile, and eliminated in the feces. Pimobendan is metabolized (demethylated) in the liver and the major metabolite desmethylpimobendan (UDCG-212) is a more potent inhibitor of PDE III (vasodilation) than pimobendan and has a half-life slightly longer than the parent drug (Yata et al., 2016) (as discussed in Section Pimobendan in Cats, cats may not produce this metabolite).

Adverse Effects

Pimobendan is well tolerated in dogs, including in animals with heart disease (Fuentes, 2004). There were initial concerns that it could produce worsening of (fatal) arrhythmias, or increase risk of atrial fibrillation in dogs with cardiomyopathy. In subsequent studies (Lake-Bakaar et al., 2015) these concerns were dismissed and no prospective, randomized, blinded trial has reported an increase in the frequency of arrhythmias in veterinary patients. Veterinary studies report improved quality and quantity of life, arguing against clinically important side effects, when pimobendan is used for treatment of canine heart failure. Furthermore, the necessity for even higher pimobendan dosages (≥0.3 mg/kg TID) in dogs that have entered ACVIM class D heart disease, have provided significant survival benefit and, in the authors' opinion, better quality of life (Ames et al., 2013). Even at very high (10 times recommended dosage) accidental over-dosing, adverse signs have been relatively modest in severity (Reinker et al., 2012). The database (November 2004 to April 2010) of an animal poison control center was searched for cases involving pimobendan toxicosis. Seven dogs that ingested between 2.6 mg/kg and 21.3 mg/kg were evaluated. Clinical signs consisted of cardiovascular abnormalities, including severe tachycardia (4/7), hypotension (2/7), and hypertension (2/7). In two dogs, no clinical signs were seen. All dogs were released from the hospital within 24 hours, although one died 3 days later.

As for all positive inotropic agents, pimobendan is *relatively* contraindicated in patients with outflow tract obstruction (e.g., HCM, subaortic stenosis, pulmonic stenosis). The inotropic effect may negatively affect dogs with early valvular lesions. In a study in asymptomatic dogs with mitral valve disease (Chetboul et al., 2007), pimobendan worsened mitral valve lesions and indices of cardiac function in dogs treated with pimobendan, compared to the group treated with the angiotensin-converting enzyme (ACE) inhibitor benazepril. The authors of the study proposed that the cardiotoxic effects were caused by an exaggerated pharmacodynamic effect, rather than from intrinsic toxicity. The importance of this finding has been diminished with the advent of the premature closing of the EPIC study (asymptomatic MMVD), discussed above.

Formulations and Dosing

Pimobendan is supplied as hard gelatin capsules (most countries) containing 1.25, 2.5, or 5 mg pimobendan. In the USA it is approved as a chewable formulation in four sizes: Vetmedin® 1.25, 2.5, 5, and 10 mg. It is not stable in suspension and should not be reformulated in this manner. The labeled dose recommendation is 0.25–0.3 mg/kg q 12 h. Initial efficacy may be enhanced by administration on an empty stomach but once steady-state is reached (a few days) it can be administered with food. Oral pimobendan solution (3.5 mg/ml and 1 mg/ml) is available in some countries (Bell et al., 2015; Yata et al., 2016). Levosimendan has been investigated as agent for treating heart failure in dogs. At this time, it is not available for clinical use.

Inotropic Agents: Inamrinone and Milrinone

Inamrinone (formerly amrinone) and milrinone are bipyridine derivatives commonly referred to as nonglycoside, noncatecholamine inotropic drugs. These compounds were discovered during an investigative search for cardiac stimulant agents that could be used to replace digitalis in the therapy of heart failure (Alousi et al., 1979). Numerous studies confirmed that inamrinone and milrinone evoke both a positive inotropic action in the heart and a peripheral vasodilator effect. The mechanism of action of the bipyridines is dissimilar to that of digitalis and does not involve adrenergic or other cell surface receptors. Rather, the cardiac inotropic and peripheral vasodilator actions of inamrinone and milrinone involve inhibition of the type III cyclic nucleotide phosphodiesterase enzyme. This enzyme is responsible for the selective metabolism of cAMP; hence, inhibition of type III phosphodiesterase by inamrinone or milrinone results in the accumulation of intracellular cAMP in cardiac and vascular tissues. Cyclic AMP subserves a positive inotropic response in myocardium and a vasodilator response in blood vessels. Because of concurrent inotropic and vasodilator actions, considerable attention has been focused first on inamrinone and later on milrinone as alternatives to digitalis in managing congestive heart failure patients (Mancini et al., 1985; Colucci et al., 1986a, 1986b).

Inamrinone (amrinone)

Although inamrinone increased cardiac contractile force and left ventricular pressure with relatively small changes in heart rate and systemic blood pressure in experimental dogs it has not been used clinically except as a last resort when other treatments have failed (Alousi et al., 1979). Adverse effects in people have prevented its routine use (Massie et al., 1985).

Milrinone

Milrinone is a structural congener of inamrinone, and the former is 20–30 times more potent than the latter. Initial studies suggested that milrinone might be relatively free of adverse side effects and could potentially be helpful in the management of heart failure in humans (Colucci et al., 1986a,b). However, studies in human patients with moderately severe heart failure indicated that milrinone was less effective than digoxin, and the combination of milrinone and digoxin was no more effective than digoxin alone. Moreover, milrinone administration was associated with an increased incidence of both ventricular and supraventricular tachyarrhythmias (DiBianco et al., 1989). In the OPTIME-CHF trial, milrinone administration had a bidirectional effect, worsening the outcome in patients with ischemic heart disease and having a neutral to beneficial effect in those with nonischemic heart disease (Felker et al., 2003).

Tachyarrhythmias were predictable as side effects of milrinone and other type III phosphodiesterase inhibitors inasmuch as their mechanism of action depends upon accumulation of cAMP. Hence, the initial enthusiasm for cardiac uses of milrinone and other type III phosphodiesterase inhibitors has decreased (Massie et al., 1985; DiBianco et al., 1989).

There is evidence that milrinone may be safe and effective in dogs with spontaneous heart failure (Kittleson et al., 1985b). Dogs may respond favorably to treatment with milrinone as the sole therapeutic agent. Positive effects were sustained for the 4 weeks of the study; however, heart failure worsened when milrinone was withdrawn but improved when the drug was reinstituted. The only apparent adverse reactions were asymptomatic ventricular dysrhythmias in two dogs. These investigators concluded that milrinone may be an effective drug for treating myocardial failure in the dog when administered orally twice daily in 0.5–1 mg/kg doses.

Clinical Use

Despite experience with oral milrinone in dogs, there is currently no approved oral formulation available. Milrinone lactate (Primacor®) is available as an injectable solution in a strength of 200 µg/ml. Milrinone is little used by veterinary cardiologists (Bonagura, 2010). Inamrinone is supplied only as an intravenous solution.

Angiotensin-Converting Enzyme Inhibitors: Enalapril Maleate and Benazepril, and Mineralocorticoid Receptor Blockers, Spironolactone

Recognition of the contribution of the renin–angiotensin–aldosterone system (RAAS) to the pathophysiology of congestive heart failure led to development of the angiotensin-converting enzyme inhibitors (ACEIs), such as captopril, enalapril, benazepril, ramipril, lisinopril, imidapril, temocapril, quinapril, alacecapril, etc. (Jackson, 2006).

Mechanisms of Action

Reduced renal perfusion during heart failure and other pathological and physiological situations evokes renin release from the juxtaglomerular apparatus (Figure 21.7).

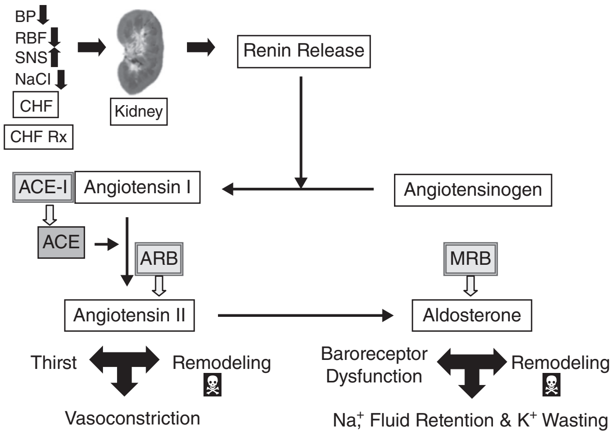


Figure 21.7 Reduction in blood pressure (BP), renal blood flow (RBF), and serum sodium concentration (NaCl), as well as activation of the sympathetic nervous system (SNS), the state of heart failure (CHF) and its treatment cause renin to be released by the juxtaglomerular apparatus, starting the cascade with angiotensinogen being converted to angiotensin I. This is followed by its conversion to angiotensin II by angiotensin converting-enzyme (ACE), and finally by stimulating the adrenal gland to secrete aldosterone. When chronic and excessive, the terminal hormones produced are toxic, particularly to heart failure patients, causing vasoconstriction, pathological remodeling of the myocardium and vessels, sodium and fluid retention, potassium wasting, and baroreceptor dysfunction. Blunting this cascade has become a major part of the treatment of cardiac disease in man and animals, using ACE-inhibitors (ACE-I), angiotensin II receptor blockers (ARB), and mineralocorticoid receptor blockers (MRB, e.g., spironolactone).

As discussed in Chapter 24, renin synthesizes the formation of angiotensin I from angiotensinogen. Angiotensin I is relatively inactive; however, it is cleaved by ACE into the potent vasoconstrictor and stimulator of aldosterone release, angiotensin II. Thus, by inhibiting ACE, ACEIs decrease the formation of angiotensin II and, through this mechanism, evoke peripheral vasodilation (relatively weak "mixed" or "balanced," arteriolar and venous, dilation). Angiotensin II-mediated release of aldosterone also is decreased by ACEI, thus facilitating sodium excretion and diuresis. Blockade of angiotensin II and aldosterone production blunts the negative effect of pathological remodeling of the heart, vasculature, and kidney in states of pathological RAAS activation (heart failure, renal failure, hypertension, and in response to off-loading therapies, such as vasodilators and diuretics)(Weber and Brilla, 1991; Schiffrin, 2006; Brown and Vaughan, 1998).

ACE is a relatively nonselective enzyme, not only converting angiotensin I to angiotensin II, but cleaving and thereby inactivating the bradykinin molecule as well. While the other effects of ACE are harmful in disease states, the increase in bradykinin is helpful as it blocks RAAS-induced vasoconstriction (via prostaglandins) and pathological remodeling.

The ACEIs commonly used in veterinary medicine, with the exception of captopril and lisinopril, are administered orally as prodrugs and converted to their active form in the liver (enalaprilat and benazeprilat). At this time, there is no clear superior ACEI, although captopril has clearly been surpassed in terms of convenience and because of its propensity to produce gastrointestinal upset.

Adverse Effects

ACEIs have the potential to produce symptomatic hypotension. This is due to the mixed vasodilatory effect of this group of drugs and is typically observed when ACEIs are used in conjunction with other off-loading therapies, such as vasodilators, diuretics, and sodium restriction. Hypotension is reversed by altering drug therapies but may be problematic in producing azotemia, inappetance, weakness, lassitude, and precipitating digitalis intoxication by reducing renal elimination. Other than at dosages 50–100 times those clinically recommended, the ACEIs are not directly nephrotoxic. The major impact of ACEI on the kidney, with clinically relevant dosages, is through production of hypotension, thereby reducing the kidney perfusion pressure and glomerular filtration rate, resulting in worsening of azotemia (MacDonald et al., 1987).

Less-common side effects include coughing and angioedema. While well-documented in people, there are no reports of these phenomena in animals. The cause for coughing is unclear, but is thought to be related to increased levels of bradykinin or resultant prostaglandins.

Veterinary clinicians have had experience with enalapril, captopril, benazepril, lisinopril, imidapril, alacepril, and ramapril. Of these, only enalapril has been extensively studied and is licensed for use in management of heart failure in the USA and benazepril has been marketed in Europe, Canada, South America, and Asia. We have learned through clinical experience with ACEIs (mainly captopril, enalapril, and benazepril in the USA) that their impact on kidney function is minimal, even in the face of severe heart failure. When azotemia is observed, ACEIs are usually administered in conjunction with diuretics and sodium restriction, often with resultant hypotension. Typically, diuretic cessation or reduction in the dosage results in the reversal of azotemia (Wynckel et al., 1998). In studies of enalapril in NYHA phase III and IV heart disease (moderate to severe heart failure), due to mitral valve regurgitation and DCM, there was actually a lower incidence of azotemia in the enalapril-treated group than the placebo-treated group (IMPROVE – Sisson et al., 1995; Cove Study Group, 1995; LIVE – Ettinger et al., 1998; Merck-Agvet, 1994). Furthermore, in a study of enalapril's role in the delay or prevention of heart failure due to naturally occurring MMVD, enalapril, at the standard dosage of 0.5 mg/kg daily, had no effect on serum creatinine concentrations as compared to placebo (Atkins et al., 2002). In fact, it is now well accepted that ACEI, administered chronically to both human and veterinary patients with naturally occurring and experimental renal failure, are beneficial (Abraham et al., 1988; Brown et al., 1999; Praga et al., 1992; Maschio et al., 1996; Grauer et al., 2000; Watanabe et al., 1999; Miller et al., 1999). Mechanisms for this improvement are postulated to be the antihypertensive effect, reduction of angiotensin II-induced mesangial cell proliferation, and renal vasodilatory effects of ACEI, the latter related to a fall in renal filtration pressure and proteinuria (Abraham et al., 1988; Praga et al., 1992; Maschio et al., 1996). Enalapril has recently been shown to reduce urine protein loss and reduce blood pressure in naturally occurring canine glomerulonephritis (Grauer et al., 2000). Likewise, benazepril reduced azotemia and proteinuria in a short-term study of experimental and naturally occurring renal insufficiency in cats(Watanabe et al., 1999) and lowered blood urea nitrogen (BUN) and creatinine concentrations and blood pressure in cats with polycystic kidney disease (Miller et al., 1999).

Efficacy

ACEIs represent a cornerstone in the chronic management of heart failure. By inhibiting the conversion of angiotensin I to angiotensin II (Jackson, 2006), they

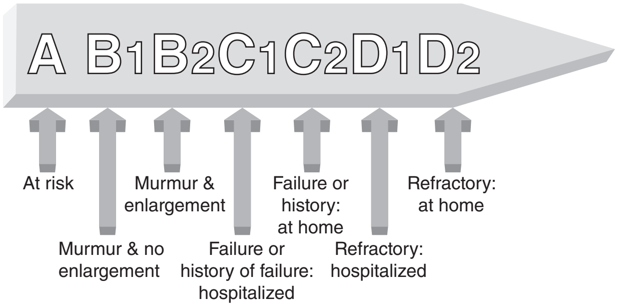

Figure 21.8 The American College of Veterinary Internal Medicine Cardiac Disease Classification scheme. Source: Atkins et al. 2009.

reduce the undesirable effects of angiotensin II (vasoconstriction; pathological remodeling with cardiomyocyte death and replacement; de novo fibrosis; and increased thirst) and aldosterone (pathological remodeling; sodium retention and potassium wasting; and baroreceptor dysfunction) recognized in congestive heart failure, hypertension, and glomerular disease.

They are indicated in virtually all cases of systolic heart failure. In subclinical MMVD (NYHA 1, ISAHC 1a and 1b, ACVIM B1 and B2) (Figures 21.8, 21.9, Table 21.4) RAAS suppression is known to be useful in asymptomatic dogs in ISAHC 1b, ACVIM B2, after there is cardiac remodeling (enlargement). ACEIs have proven useful in the management of systemic hypertension, clinical and subclinical cardiac disease, and proteinuric renal disease (Grauer et al., 2000; Atkins and Haggstrom, 2012; O'Grady et al., 2009).

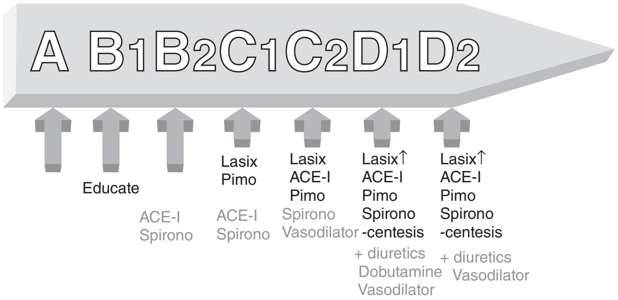

Figure 21.9 The American College of Veterinary Internal Medicine Classification Scheme with recommendations of the Consensus Committee on management of myxomatous mitral valve disease in dogs. Unanimous recommendations of the Committee are in bold black type, while the grey type represents the majority recommendations of that group, as well as the recommendations of the authors. Since the ACVIM Consensus Panel made its recommendations, two studies have been published which will likely impact this scheme. A European study demonstrated that the combination of benazepril and spironolactone were efficacious in treating dogs with heart failure (Bernay et al., 2010). The EPIC Trial demonstrated that pimobendan was effective in dogs in Stage B2 heart disease, prolonging the time to heart failure or cardiac death (Boswood et al., 2016). ACE-I, angiotensin converting-enzyme inhibitor; Spirono, spironolactone; Pimo, pimobendan; -centesis, thoracocentesis and/or abdominocentesis; Lasix, furosemide. Source: Atkins et al. 2009.

In NYHA phase III and IV heart disease in dogs (moderate to severe heart failure; Table 21.4), due to MMVD or DCM, enalapril improved survival by >100% as well as reducing pulmonary edema and, improving quality of life scores (IMPROVE – Sisson et al., 1995; Cove Study Group, 1995; LIVE – Ettinger et al., 1998). Exercise capacity is also improved in dogs with experimental mitral insufficiency (Hamlin et al., 1996).Benazepril has likewise been shown to improve survival (BENCH Study Group, 1999). The multicenter trials cited examined the ability of ACE inhibition to augment digitalis and diuretic therapy, rather than therapeutic benefits from enalapril alone. Nevertheless, these studies yielded convincing evidence that inhibition of ACE with enalapril improves quality of life and delays mortality in dogs with heart failure. It is clear that enalapril (and, likely the ACEI class) is beneficial in the management of heart failure when added to conventional therapy. There has been virtually no study of ACEI and inodilators being used together.

Preclinical heart disease: Enalapril has been studied in two placebo-controlled, randomized, double-blind clinical trials assessing its ability to slow the progression to heart failure in dogs with MMVD. The two studies were similarly designed, utilizing asymptomatic MMVD patients, the onset of pulmonary edema as the primary endpoint, and the ACEI, enalapril, versus placebo in a double-blinded, prospective trial (SVEP – Kvart et al., 2002; VETPROOF – Atkins et al., 2007). The SVEP trial and the VETPROOF had differing results because of differing study design. Both studies are useful to our understanding of the role of ACEI prior to the onset of heart failure in MMVD. Results of the SVEP trial argue strongly that, at the dosage evaluated, there is little to no benefit with ACE inhibition in a population of dogs with (107) and without (122) radiographic evidence of remodeling. The 5-year VETPROOF demonstrates a modest benefit in delaying the onset of heart failure with an additional 3-year follow-up substudy demonstrating a treatment benefit in delaying all-cause mortality; the latter study should ideally be repeated, with all-cause mortality as the primary endpoint. In the all-cause mortality substudy of 96 study participants followed to their deaths, it was demonstrated that a longer-term benefit (9 months) with ACEI therapy ($P < 0.02$) (Atkins and Keene, 2009).

Feline studies: In a retrospective study of cats presenting with HCM, enalapril therapy improved echocardiographic parameters (Rush et al., 1998). However, a larger prospective, blinded study (MacDonald et al., 2006), in which ramipril, administered for 1 year to Maine Coon and Maine Coon cross-bred cats with HCM, did not lead to a significant difference in LV mass, diastolic function, or BNP or aldosterone concentrations when were compared to controls.

Drug Interactions

A complete list of pharmacokinetic drug interactions is provided in the manuscript by Shionoiri (1993). Interactions that affect renal function are covered by Loboz and Shenfield (2005). ACEIs are used with other cardiovascular drugs (including diuretics) safely. However, ACEIs will potentiate the effect of diuretics and these drugs should be used together cautiously. Often times, the dosage of diuretic can (and should) be reduced with concomitant ACEI therapy.

When ACEIs are administered concurrently with nonsteroidal antiinflammatory drugs (NSAIDs), the latter may diminish ACEIs beneficial effect by blocking formation of prostaglandin, as some of the antihypertensive effect of ACEI is caused by generation of prostaglandins (Guazzi et al., 1998; Davie et al., 2000). NSAIDs also have been suggested to increase the risk of kidney injury (Loboz and Shenfield, 2005). Only one study examining this combination has been published for dogs, in which it was concluded in that tepoxalin did not alter renal function in healthy Beagle dogs receiving an ACEI (Fusellier et al., 2005). This has not been determined for other NSAIDs.

Use of ACE Inhibitors in Chronic Kidney Disease

As reviewed by Lefebvre and Toutain (2004), ACEIs can be beneficial in chronic kidney disease (CKD) because they reduce intraglomerular pressure, slow progression of lesions, and decrease proteinuria. These authors have documented the changes in disposition of ACEI in animals with renal impairment (Lefebvre and Toutain, 2004; Lefebvre et al. 2006). In dogs and cats, enalaprilat (active metabolite of enalapril) is predominantly cleared by the kidneys. Benazeprilat is excreted in the bile as well as in the urine, while enalaprilat is excreted solely by the kidneys. In the situation of renal dysfunction, benazeprilat serum concentrations are essentially unchanged from those expected in normal dogs (Toutain et al., 2000). Enalaprilat serum concentrations, however, with no alternative route for elimination, are elevated in the situation of renal dysfunction. Therefore, under these circumstances, benazepril is more predictable in terms of serum concentrations.

In cats with reduction in glomerular filtration rate, there was no alteration in clearance of benazeprilat(Lefebvre et al., 1999; Toutain et al., 2000; Brown et al., 2001).

ACE Inhibitors Currently in Use

Enalapril (Enacard®, Vasotec®, generic) has been approved for the treatment of heart failure in dogs in most countries, including the USA (Enacard®), but is no longer marketed in this country and the human generic drug is used. The dosage of enalapril used in the treatment of heart failure is 0.25–0.5 mg/kg q 12–24 h PO, whereas for systemic hypertension and proteinuria there is a wider rage of 0.25–1.0 mg/kg q 12–24 h PO. The dosage in cats is 0.25–0.5 mg/kg q 12–24 h.

Benazepril (Fortekor®, Lotensin®) has been approved for use in dogs in Canada, Europe (Fortekor®), South America, and Asia, and has been investigated in the USA for use in cats and dogs, at a dosage of 0.25–0.5 mg/kg q 12–24 h PO. Imidapril has been approved for the treatment of heart failure in dogs in the UK (Prilium®) at 0.25 mg/kg q 24 h PO. Ramipril (Altace®, Vasotop®) has been approved for use in dogs in the UK (Vasotop®). The dosage is 0.125–0.25 mg/kg q 24 h PO (starting at the lower end of the dose range and titrating upwards). Lisinopril (Prinivil®, Zestril®) has also been investigated in animals, but is not in common use. The dosage used in dogs is 0.5 mg/kg q 12–24 h, PO. The dosage in cats is 0.25–0.5 mg/kg q 24 h.

A combination of benazepril and spironolactone (Cardalis®) has now been approved for use in the EU for dogs in heart failure. This should provide a useful and convenient addition to the arsenal for management of heart failure, hypertension, and possibly proteinuric renal disease. US studies are in progress at the time of this writing. Cardalis® is supplied as 2.5 : 10, 5 : 20, 10 : 80 (mg benazepril : mg spironolactone) chewable tablets for once-daily use.

Mineralocorticoid Receptor Blockers

At the time of this writing, there are two mineralocorticoid receptor blockers on the market, eplerenone and spironolactone. Eplerinone is a human drug used to avoid some of the endocrine side effects of spironolactone. It is not used in veterinary medicine and is expensive, therefore will not be included in this discussion.

Spironolactone is a synthetic 17-lactone drug that is a competitive aldosterone receptor (mineralocorticoid receptor blocker, MRB). The result of this antagonism of mineralocorticoid receptor in distal renal tubule cells is an increase in urinary Na^+ and H_2O excretion and a decrease in K^+ excretion. In the dog, spironolactone is relatively quickly absorbed through the gastrointestinal tract into the plasma and is then converted to several active metabolites (Sadée, 1972; Karim et al., 1976). The bioavailability in the dog is highest when given with food, reaching 80–90% (Guyonnet et al., 2010). Using an experimental model of hyperaldosteronism, mimicking that in heart failure, Guyonnet and colleagues (2010) found that the spironolactone dosage of 2 mg/kg once daily restored the urinary Na^+/K^+ ratio to near normal.From this result and analysis of pharmacokinetic and pharmacodynamic data from this preclinical trial, the authors suggested that the optimal dosage of spironolactone in the dog is 2 mg/kg once daily.

As a weak, potassium-sparing diuretic (diuretics are discussed in Chapter 24), spironolactone was initially used to provide sequential nephron blockade and combat hypokalemia resulting from the use of loop and thiazide diuretics. However, current use focuses on the antagonism of aldosterone, which may have long-term benefits. Aldosterone has been implicated in the pathological remodeling (inflammation, hypertrophy, fibrosis) of cardiovascular and renal tissues (Ovaert et al., 2009; Hezzell et al., 2012). Because of this, the primary rationale for adding spironolactone as adjunctive therapy for heart failure is now mineralocorticoid receptor (specifically, aldosterone) blockade. Mineralocorticoid receptor blockade is now considered standard of care in humans with heart failure and low ejection fraction (McMurray et al., 2012; Yancy et al., 2013). The benefit seen with additional RAAS blockade in heart failure supports the concept of aldosterone breakthrough, discussed in Section Clinical Use. A similar study in 212 dogs with naturally occurring MMVD and heart failure showed a 69% reduction in risk of cardiac morbidity and mortality when spironolactone was added to standard therapy (ACEI, furosemide, with or without digoxin), as compared standard therapy alone (Bernay et al., 2010). A separate safety analysis of dogs involved in the aforementioned study showed that dogs receiving spironolactone, in addition to standard therapy, were not at higher risk of adverse events (death from renal disease, variations in serum Na^+, K^+, urea nitrogen, and creatinine) when compared to dogs receiving placebo and standard therapy (Lefebvre et al., 2013). Finally, spironolactone in combination with ACEI therapy appears to be safe when used to treat dogs with naturally occurring asymptomatic MMVD, as well those with occult DCM, without preexisting azotemia (Thomason et al., 2007, 2014).

Clinical Use

A consensus statement of the American College of Veterinary Internal Medicine, generating guidelines for the therapy of dogs with MMVD (Atkins et al., 2009), recommended the use of spironolactone as an adjunctive therapy in dogs with ACVIM stage D2 (refractory, with home therapy possible) heart failure (Figures 21.9 and 21.10). A majority of panelists also used spironolactone in the therapy of stage C2 (dogs previously stabilized with in-hospital heart failure therapy or clinical signs of heart failure, mild enough to be treated at home (Figure 21.9). A minority of panelists advocated the use spironolactone in dogs with ACVIM stage B2 (cardiac enlargement, but prior to onset of heart failure) MMVD.

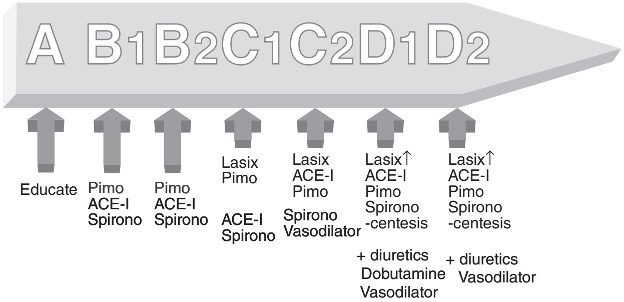

Figure 21.10 The American College of Veterinary Internal Medicine Cardiac Disease Classification scheme with the authors' treatment recommendations for dilated cardiomyopathy. See Figure 21.9 for abbreviations.

Spironolactone is approved within the European Union as adjunctive therapy in the treatment of canine heart failure, secondary to MMVD. Clinical trials are currently underway to evaluate the effects of spironolactone in combination with ACEI in the treatment of stage B2 and C1 MMVD dogs (ongoing US placebo-controlled, double-blind study of spironolactone and benazepril versus benazepril alone in dogs with MMVD and first-time heart failure, sponsored by CEVA Santa Animale with expected completion in 2017) (Borgarelli, 2011). There is no consensus regarding the use of spironolactone in other diseases, such as DCM and congenital heart disease, despite its having been used for decades to treat canine heart failure, secondary to a variety of causes.

Preliminary data from the authors' clinics suggest that aldosterone breakthrough occurs in dogs with heart failure due to naturally occurring heart disease and that the incidence is approximately 40%. Furthermore, it appears that aldosterone breakthrough may occur quite early in the disease course (Bomback and Klemmer, 2007; Lantis et al., 2014). Monitoring of urine aldosterone : creatinine (Gardner et al., 2007), may therefore help optimize an individual patient's pharmacotherapy and improve RAAS blockade (i.e., determine if spironolactone should be added as an adjunctive therapy).

Use in cats: Aldosterone has been found to be elevated in Maine Coon cats with asymptomatic HCM (MacDonald et al., 2006) and the use of spironolactone (2 mg/kg/day for 4 months) in the therapy of asymptomatic HCM in cats has been evaluated (MacDonald et al., 2008). Unfortunately, this study did not show reduction in left ventricular mass or improvement in an echocardiographic parameter of diastolic function and four of the 13 spironolactone-treated cats developed ulcerative facial dermatitis. A double-blinded, placebo-controlled clinical trial, evaluating the use of spironolactone in cats with heart failure due to HCM is currently under way (James et al., 2013). It is worth noting that, at interim analysis (n = 16 cats enrolled), no cat receiving spironolactone (1.3–2.2 mg/kg once daily) had experienced ulcerative facial dermatitis.

In conclusion, based on clinical and research data, the authors utilize spironolactone in virtually all instances in which ACEIs are employed. This would include dogs with ACVIM stage B2 MMVD (cardiac enlargement, but prior to onset of congestive heart failure (pulmonary edema); Figure 21.10); dogs with ACVIM stage C2 and D2 MMVD (at-home therapy of congestive heart failure; Figure 21.10); in systemic hypertension; in occult and florid DCM; and in proteinuric renal disease. At the current time, as data on MRB efficacy are pending, we do not feel that there is adequate evidence for the routine use of spironolactone in cats at this time.

Other Vasodilators: Prazosin, Hydralazine, Calcium Channel Blockers, Nitrovasodilators, Sildenafil, and Carvedilol

Vasodilators are characterized as: (i) "venous dilators" or "venodilators" (preload reducing), with nitroglycerin being a prime example – useful for signs of congestion; (ii) "arteriolar dilators" or "arteriodilators" (afterload reducing) include hydralazine and amlodipine – useful for low output signs (and for signs of congestion); and (iii) "mixed" or "balanced" vasodilators, which dilate both arterioles and veins, include the ACEIs, prazosin, pimobendan, and nitroprusside, useful for both congestive and low output signs. All, except pimobendan, also have the potential to cause hypotension and, hence, impaired renal perfusion. When used with other off-loading therapies (e.g., furosemide), hypotension and azotemia are more likely to result.

This group of drugs has been used extensively as treatment for heart failure to "off-load" or "unload" the failing heart (Hamlin, 1977; Zelis et al., 1979; Remme, 1993). The rationale is that decreasing the work load of the heart is better for the patient than administering a positive inotropic agent with toxic potential (i.e., digitalis) and which typically increases MVO_2 (inodilators, such as pimobendan, being an exception). If systemic arterial pressure (a component of left ventricular afterload) is reduced by a vasodilator drug, the left ventricle ejects blood into a circuit with lowered resistance. Further, peripheral venodilation diverts blood from the pulmonary to the systemic vasculature. This response is antagonistic to the formation of pulmonary edema, because it tends to restrict venous return to the heart (i.e., ventricular preload). Left ventricular size and wall tension decrease in response to reduction in ventricular preload and afterload. Myocardial oxygen demands decrease accordingly as the workload of the heart is reduced; cardiac output and hemodynamics should improve (Packer, 1984; Abrams, 1985).

Before initiating vasodilator therapy in treating congestive failure in animals, the clinician should be aware of potential problems; for example it has been assumed that drug-induced vasodilation would automatically increase peripheral perfusion and thereby increase oxygen availability to all tissues. However, vasodilator agents of the nitroglycerin type exert a predominant reduction in peripheral venous resistance as compared to arteriolar resistance. Pooling of blood in the venous capacitance beds in no way ensures increased perfusion of all tissues. Vasodilators are beneficial to the failing heart because they decrease cardiac workload, not by directly improving peripheral perfusion but because of vascular dilation. Furthermore, if arterial pressure is critically decreased, blood flow through the coronary and renal vascular beds may be compromised further. Reflex tachycardia accompanied by increased myocardial oxygen demand is another potential problem associated with fall in systemic blood pressure.

Prazosin

Prazosin (Minipress) is an α_1-adrenergic selective blocking agent (Chapter 7). Prazosin can be an effective vasodilator through the adrenergic blocking properties on vascular smooth muscle, but it is little used in veterinary cardiology. This drug may be useful in the treatment of renal hypertension (Zimmerman and Largent, 1983) and treatment of vesicourethral reflex dyssynergia in dogs (Haagsman et al., 2013). In dogs, prazosin undergoes hepatic metabolism with biliary excretion being the major route of elimination and 50% metabolized through first-past metabolism. Urinary excretion of this drug appears to be low (Rubin et al., 1979).

Hydralazine Hydrochloride

Hydralazine hydrochloride, USP (Apresoline®), is an arteriolar dilator that has undergone limited study in dogs with volume-overload heart failure (Kittleson et al., 1983; Häggström et al., 1996) and experimental heartworm disease with pulmonary hypertension (Atkins et al., 1994). Through its effect on systemic arterial beds, hydralazine reduces impedance, peripheral and pulmonary vascular resistance, and lowers impedance to left ventricular ejection. Stroke volume and cardiac output increase proportionately, thereby initiating hemodynamic improvement.

Beneficial effects of hydralazine are manifested in the management of congestive heart failure, secondary to MMVD. In this pathophysiological state, forward left ventricular stroke volume is reduced owing to a regurgitant fraction being pumped backward through the incompetent AV valve into the left atrium. By lowering systemic impedance to left ventricular ejection, hydralazine increases forward stroke volume and thereby reduces the regurgitant fraction. End-systolic volume and cardiac size are reduced because more blood is pumped from the cardiac chambers per beat. Reduction in cardiac size leads to commensurate decreases in wall tension (afterload) and myocardial oxygen consumption. Also, importantly, it reduces the size of the orifice of the incompetent mitral valve and hemodynamic improvement has been demonstrated in dogs with volume-overload congestive heart failure, caused by mitral valve regurgitation (Kittleson et al., 1983; Häggström et al., 1996). However, there are no outcome trials published to date. Hydralazine is likely effective in other volume overload states such as patent ductus arteriosus, aortic insufficiency, or septal defects.

Pharmacokinetics

Hydralazine is absorbed rapidly after oral administration in dogs, its onset of action is within 1 hour, and peak response at 3–5 hours. The drug undergoes extensive hepatic metabolism during its initial passage through the liver. Administration of hydralazine with food in dogs reduces its bioavailability (Semple et al., 1990). There is evidence that uremia in some way affects biotransformation of hydralazine, so that blood concentrations may increase in uremic patients.

Clinical Use

A recommended dosage for hydralazine in dogs involves the initial oral administration of 1 mg/kg; this dose can be adjusted upward, depending upon evidence of clinical improvement, but should not exceed 3 mg/kg. Although doses have been published for cats, it is not currently recommended for treatment.

The therapeutic response in dogs generally lasts 11–13 hours; thus twice-daily administration is suggested as the standard (Kittleson, 1983).

Adverse Effects

Important adverse effects of hydralazine therapy in humans are tachycardia and hypotension. It was reported that hypotension was not a problem in dogs when hydralazine dosage was titrated carefully against signs of clinical improvement; however, tachycardia does seem to be a common untoward development in dogs, treated with hydralazine (Kittleson et al., 1983). Because tachycardia increases myocardial oxygen consumption and may lead to cardiac decompensation, heart rate should be monitored during therapeutic implementation with hydralazine or any other vasodilating drug.

Concomitant administration of a beta-blocking drug might reduce the reflex tachycardia produced by hypotensive reactions to hydralazine. On the other hand, the potential negative inotropic response to cardiac beta-receptor blockade may exacerbate heart failure and/or worsen hypotension (see Chapter 7).

Calcium Channel Blocking Drugs

These agents suppress calcium ion (Ca^{++}) influx through plasma membrane channels in cardiac tissues, vascular smooth muscle, and other excitable cell types (Katz, 1985; Allert and Adams, 1987; Opie, 1984). The resulting decrease in intracellular Ca^{++} concentration leads to characteristic changes in physiological activity of affected tissues, including reduction in myocardial contractility, vasodilation in coronary and peripheral arterial beds, lowered impedance to left ventricular ejection, reduced myocardial oxygen demand, and slowed AV impulse conduction. Because of this diverse pharmacological profile, Ca^{++} channel blockers have been studied extensively for therapeutic application in a wide spectrum of cardiovascular disorders. Drugs of this group have been approved for the management of ischemic heart disease, hypertension, and some forms of cardiac dysrhythmias in human medicine. Other indications in people include obstructive cardiomyopathies, asthma, and cerebral ischemia (Stone and Antmann, 1983; Conti et al., 1985). Less is known about the clinical application of Ca^{++} channel blockade in veterinary medicine (Adams, 1986; Novotny and Adams, 1986; Johnson, 1985; Bright, 1992). The greatest experience has been with amlodipine, primarily in the management of systemic hypertension (Henik, 1997; Snyder, 1994) and with diltiazem, used to slow AV conduction (Gelzer et al., 2009) (thereby slowing ventricular response to atrial fibrillation or supraventricular tachycardia); to break supraventricular tachycardia; and as a lusitropic agent in cats with HCM (Bright, 1992). Amlodipine is also used in the treatment of heart failure to unload the ventricle(s), reducing cardiac size, reducing AV valvular insufficiency, improving forward cardiac output, and reducing impingement of an enlarged heart on the airways. The rationale for Ca^{++} channel blocking drugs in cardiovascular therapeutics in animals was summarized by Allert and Adams (1987). The use of Ca^{++} blocking agents as Class IV antiarrhythmics and electrophysiological properties in treating supraventricular tachyarrhythmias is addressed in Chapter 22.

Fundamentals of Ca^{++} Channel Blockade

Channel blockers are a heterogenous group of drugs that can be classified into two groups. The dihydropyridine calcium channel blockers (amlodipine, nifedipine) have greater vascular selectivity whereas the nondihydropyridine calcium channel blockers (diltiazem, verapamil) have greater selectivity for nodal and myocardial tissues. Their commonality is that they all selectively inhibit the L-type Ca^{++} channel – preventing its opening in smooth muscle and/or the myocardium. The dihydropyridine group (verapamil and diltiazem) are discussed more extensively in Chapter 22 of this book.

The calcium channels are protein moieties embedded within and spanning the permeability barrier of the phospholipid plasma membrane biolayer. Calcium channel blocking drugs induce negative inotropic effects in the heart by reducing transsarcolemmal influx of activator Ca^{++}.

Contraction of vascular smooth muscle is mediated by Ca^{++} and also depends on the influx of Ca^{++} through cell membrane channels (Somlyo, 1985). Therefore, Ca^{++} channel blockade in the vasculature evokes smooth muscle relaxation and a vasodilatory response. The resultant peripheral vasodilation, and accompanying decrease in peripheral vascular resistance, lowers impedance to left ventricular ejection, thereby reducing ventricular wall tension (afterload) during ejection.

Adverse Effects

Although the negative inotropic effects and vasodilator actions of Ca^{++} channel blockade can benefit hemodynamics by reducing cardiac workload, these same cardiovascular depressant responses obviously carry the risk of exacerbating hypotensive crisis. Adverse circulatory side effects of Ca^{++} channel blockade include a negative inotropic effect, with reduced cardiac output and hypotension, particularly with concurrent off-loading therapies (diuretics, ACEIs, vasodilators). This combination of effects can result in decompensation of preclinical or compensated heart failure Hypotension may also complicate treatment of patients *not* in danger of heart failure, resulting in lassitude, anorexia, collapse, and azotemia. Other potential side effects are sinus bradycardia and heart block, attributable to direct depression of sinoatrial firing rate and AV conduction, respectively.

Clinical Use

Antiarrhythmic applications are discussed in Chapter 22. For example, diltiazem is a common treatment for controlling heart rate in cats with HCM (Bright, 1992), and can be used in dogs for treating atrial fibrillation. When considered for HCM in cats, long-acting diltiazem is an attractive alternative. Based on the author's work (Johnson et al., 1996), conventional diltiazem should be administered at 7.5 mg TID and long-acting diltiazem at 45 mg q 24 h.

Dilacor® XR has the advantage of availability in capsules which contain three or four time-release tablets, as compared to the granules of the long-acting form. Based on studies with this product (Wall et al., 2005), either 30 or 60 mg of extended-release diltiazem tablets PO, once daily, can be administered, but Dilacor® XR administered at 30 mg BID can be effective without the untoward events.

Because other vasodilator drugs are available in veterinary medicine, (discussed in this chapter) amlodipine is rarely used in the management of heart failure. Amlodipine is the preferred drug for management of systemic hypertension in cats because it is longer-acting than other dihydropyridines (Snyder, 1994).

Nitrovasodilators: Nitroglycerin, Isosorbide Dinitrate, and Nitroprusside

The organic nitrates are nitrogen esters that exert their effect by acting as an exogenous source for nitric oxide. Nitric oxide is now known to be endothelium-derived relaxing factor (EDRF), an endogenous vasodilator. The nitrate vasodilators are esters of nitrous acid. They are metabolized to inorganic nitrite and denitrated metabolites.

Mechanism of Action

Nitrites, organic nitrates, and nitroso compounds all act to activate the enzyme *guanylate cyclase*. The resultant increase in intracellular cyclic-GMP (3,5-guanosine monophosphate) subsequently acts to inhibit contraction of vascular smooth muscle. This mechanism may involve a decrease in the availability of intracellular Ca^{++} in vascular smooth muscle cells or may interfere with the myosin–actin interaction (Opie and Gersch, 2009). Nitrates may also stimulate synthesis of the vasodilator prostaglandins, PGI_2 and PGE. Nitrates relax smooth muscle in both arteries and veins, but they are often used clinically as *preload* reducers. They decrease myocardial O_2 requirements (decrease workload of heart) and pool blood in the splanchnic vessels to reduce congestive signs in heart failure. They are commonly used to manage human patients with angina pectoris (chest pain caused by coronary artery disease), as coronary vasodilators and possibly by reducing cardiac work through reduction in preload.

Pharmacokinetics

Nitroglycerin and other nitrovasodilators are metabolized quickly with half-lives of only a few minutes. Nitrates have significant *first-pass effects*, and metabolites are one-tenth or less the potency of the parent drug. These drugs are, therefore, administered either topically, sublingually, or intravenously to avoid first-pass metabolism by the liver. In dogs receiving topical 2% nitroglycerin ointment applied to the pinnae at a dosage of 0.25 cm/kg or an equal amount of petrolatum, splenic dimension increased by an average of 7% in treated dogs as compared to no change in the placebo-treated dogs

(Parameswaran et al., 1999). Enlargement of the spleen was apparent at approximately 8 minutes, peaking at approximately 15 minutes. This occurred without elevation in splenic pressure, indicating relaxation of vascular smooth muscle in the spleen.

Nitrovasodilators in Clinical Use

Nitrovasodilators are available as ointments, creams, sublingual tablet, lingual spray, or buccal tablet.

Nitroglycerin (NitroBid®, Nitrol®, Minitran®, Nitro-Dur® and generic) is applied topically (as a 2% cream, 2% ointment, or 0.2, 0.4, 0.6, and 0.8 mg/h patch), The half-life is 1–3 minutes. An international group of veterinary cardiologists (ISACHC, 2006) recommends a topical nitroglycerin dosage of 4–15 mg q 6–12 h for dogs and 3–4 mg q 6–12 h for cats. It is usually applied to an area on the patient that lacks hair and where the patient will not lick it off (such as pinnae of ears or shaved portion of the body; most patients receiving nitroglycerin are not grooming). This topical formulation of nitrate vasodilation, administered TID, is preferred by the authors to supplement management of acute heart failure.

Isosorbide dinitrate (Isordil®) is available as an oral tablet (even though it has poor systemic availability), topical ointment, and lingual spray at a dosage is 2.5–5.0 mg/dog). Isosorbide mononitrate (IS-5-MN) may have better absorption and longer half-life. At both IV and PO doses of 3 mg/kg of IS-5-MN, the main metabolite of isosorbide-dinitrate, showed that the decrease in systolic blood pressure was closely correlated with the log plasma concentration (Sponer et al., 1984). Bioavailability was estimated at 71.5%. The half-lives for the distribution and elimination phases were approximately 6 minutes and 1.5 hours, respectively, the latter being only one-third of that obtained in man. Subsequently, dogs were given five different dosages of IS-5-MN orally (3.125–50 mg/dog) and showed a peak plasma concentration and area under the curve proportional to the dosage, whereas the terminal half-life did not differ markedly. The minimum plasma concentration for a hemodynamic effect was estimated to be 100 ng/ml.

Some studies in experimental dogs using oral administration of long-acting isosorbide dinitrate at 1–2 mg/kg had beneficial effects (Yamamoto et al., 2013). However, others have found less promising results. Adin and associates evaluated 5-isosorbide dinitrate in normal dogs and dogs in heart failure, using a dosage of 2, 3, and 4 mg/kg PO or placebo on separate days (Adin et al., 2001). Investigators were unable to detect a shift in blood volume with oral 5-isosorbide dinitrate administration at any dose tested in either group, despite adequate drug levels. The authors questioned the benefit of this compound in the treatment of dogs with congestive heart failure.

Sodium nitroprusside (Nipride®) is a potent, direct-acting mixed vasodilator, administered as a CRI because of its short half-life. Tolerance does not develop to nitroprusside, relative to other nitrate compounds, because it provides intracellular nitric oxide. It is administered, in 5% dextrose, at an infusion rate of 0.5–10 μg/kg/min (beginning at the lower dosage and titrating upwards, as needed) to veterinary patients, while monitoring blood pressure to avoid hypotension. The risk of hypotension can be lessened and additional benefit realized when used with dobutamine infusion or pimobendan PO or IV. It is supplemental to loop diuretic administration, lowering left and right heart filling pressures, systemic and pulmonary vascular resistance, ventricular afterload, and pulmonary edema. Cyanide toxicity can develop in patients in which renal elimination is compromised because sodium nitroprusside is rapidly metabolized to cyanide and thiocyanate.

Although there are limited publications on its effect and use in normal dogs or those in congestive heart failure, the ACVIM Consensus Committee on MMVD reached consensus on its use emergent congestive heart failure (ACVIM Stages C and D; Figure 21.8, 21.9) (Atkins et al., 2009). A small case series showed benefit with nitroprusside infusion in dogs with fulminant, unresponsive (furosemide, nitroglycerin, and oxygen, with no mention of ACEIs or inotropic agents) pulmonary edema due to MMVD (Greer et al., 2004). Eight of 10 dogs were released from the hospital, seven receiving from 1 to 3 (mean 1.75) μg/kg/h and one receiving 5 μg/kg/h. Infusion was reduced or stopped if blood pressure fell below 90 mmHg. Infusions were continued for an average of 14 hours and tapered over 2–3 hours.

Clinical Uses

In people, the organic nitrates are primarily used for the relief of anginal pain (angina pectoris) (Parker and Adams, 1977). Their use in veterinary medicine is limited because the dosage forms available can be inconvenient to use and the duration of action is brief. Nevertheless, they may be helpful for vasodilation and the acute treatment of pulmonary edema associated with congestive heart failure. Topical nitroglycerin ointment (2%) is typically used in a semiquantitative fashion:

cats: 0.3 cm strip (1/8 inch),
small dogs: 0.6–1.2 cm strip (1/4 to 1/2 inch),
medium dogs: 1.2–2.5 cm strip (1/2 to 1 inch),
large dogs: 2.5–5.0 cm strip (1 to 2 inch).

It is applied topically (usually to the inner ear flap) q 8 h, for the acute management of congestive heart failure. After 24 hours, because of concerns or tolerance, the drug is stopped if the patient's condition allows, or withdrawn for 8 hours and then continued at the same dosage at "8 hours on – 8 hours off". The drug is rarely dispensed but, if so, it can be used to treat orthopnea in heart failure patients, by administering it at bedtime once daily. Owners should be instructed to wear exam gloves when applying the ointment and to wash hands thoroughly afterwards.

Tolerance

Tolerance to nitrovasodilators develops with repeated administration. The mechanism is suspected to be a progressive depletion of sulfhydral groups necessary for the formation of nitric oxide. Efficacy is improved if the drug is used intermittently instead of continuously because intermittent use allows time for regeneration of sulfhydral groups. Optimum intermittent use is to provide a nitrate free interval of 8 hours or more during the day.

Adverse Effects

The most common and limiting side effect of these drugs is hypotension. Methemoglobinemia can occur with accumulation of nitrites but, both this and cyanide poisoning are extremely uncommon, as this therapy is usually used in the short-term management of acute heart failure requiring hospitalization.

Phosphodiesterase V Inhibitors: Sildenafil

Sildenafil (Viagra®) is an orally active PDE V inhibitor. Phosphodiesterase V is found in relatively high concentration in lung and penile erectile tissue and levels are elevated in humans with pulmonary hypertension (PHT). Type V phosphodiesterase inhibitors prevent degradation of cyclic guanosinemonophosphate-specific phosphodiesterase-5 (cGMP), resulting in relaxation of smooth muscle in pulmonary vasculature and, to a lesser degree, systemic vessels. This enhances nitric oxide-mediated pulmonary vasodilation and may provide additional beneficial effects on vascular remodeling and cardiac function (Takimoto et al., 2005). However, a canine study looking specifically at sildenafil's effect on cardiac function did not demonstrate inotropic benefit (Dias-Junior et al., 2006).

Pulmonary hypertension, a clinically important disease associated with high morbidity and mortality in dogs, is most often a sequelae of other disease processes (chronic obstructive pulmonary disease and heartworm disease), thereby requiring a balanced therapeutic approach which targets both the underlying disease and palliation of clinical signs. An important goal of therapy is to reduce pulmonary artery pressures. Early vasodilators, however, have had no preferential effect on pulmonary vasculature and thus have had questionable benefit, as well as the potential to worsen the clinical signs of pulmonary hypertension by producing systemic hypotension.

Sildenafil is currently the most extensively researched of the PDE V inhibitors, and has been shown to improve erections, as well as exercise tolerance and quality of life in humans with PHT, resulting in FDA approval for its use in erectile dysfunction and PHT. Although, still expensive, sildenafil is now available as a generic preparation.

Pharmacokinetics

There are little published data on sildenafil in the dog. Incompletely described pharmacokinetic properties include T_{max} of 1 hour or less. Bioavailability is attenuated by presystemic hepatic metabolism. The volume of distribution is 5.2 l/kg, with plasma protein binding of 84%. The dog has an elimination half-life of 6.1 hours. After single oral or intravenous doses of [^{14}C]-sildenafil, the majority of radioactivity was excreted in the feces (Walker, 1999; Sugiyama, 2001; Al-Mohizea et al., 2015).

In normal human subjects, sildenafil is rapidly absorbed after oral administration, with absolute bioavailability of about 40%, due to the extensive first-pass metabolism. It is eliminated predominantly by hepatic metabolism (mainly by cytochrome P450 3A4) and is converted to an active form. Sildenafil and its metabolite have terminal half-lives of approximately 4–5 hours. The maximum observed plasma concentration of sildenafil is reached within 30–120 minutes (median 60 minutes) of an oral dosing in a fasting state (Al-Ghazawi et al., 2010).

Efficacy

Well-controlled dose studies of vasodilator effects of sildenafil are lacking in the veterinary literature; however, there are three small clinical studies, one being placebo controlled (Dias-Junior et al., 2006; Bach et al., 2006; Kellum and Stepien, 2007). The dose used is approximately 2 mg/kg sildenafil every 8–24 hours. These studies show improvement in pulmonary hypertension or quality of life scores.

In naturally occurring PHT in dogs with concurrent MMVD, dosage of 1 mg/kg TID sildenafil (Brown et al., 2010), with concomitant but variable use of furosemide, enalapril, pimobendan, digoxin, spironolactone, and thiazide diuretics, produced improvements in pulmonary pressures. Exercise capacity was significantly greater and quality of life scores significantly higher in dogs receiving sildenafil than in dogs receiving placebo. The authors concluded that sildenafil decreases systolic pulmonary arterial pressure in dogs with PAH and its use is associated with increased exercise capacity and quality of life, when compared to treatment with placebo. No adverse effects were noted.

Because of the variability and complexity of the potential causes of PHT, additional harmful effects of the underlying disease, and the systemic response to pulmonary hypertension (e.g., congestive heart failure), sildenafil is often used in combination with other medications, including conventional heart failure therapeutics, such as diuretics, ACEIs, and pimobendan (Hoskins, 2006). While adverse side effects with long-term therapy have been minimal or unrecognized, long-term studies are lacking.

Carvedilol

This compound has been approved for use in humans to treat hypertension and heart failure. Antiarrhythmic effects are discussed in Chapter 22. It is both a nonselective β_1 and β_2-receptor antagonist and an α_1-receptor antagonist (see Chapters 7 and 22 for more complete discussion). The ratio of β_1/β_2 to α_1-receptor antagonist potency for carvedilol is 10 : 1. Thus, this agent should reduce myocardial workload by lowering heart rate and peripheral vascular resistance. Carvedilol is also an antioxidant and its beta-blocking effects have potential beyond heart rate control and vasodilation. It is well accepted in human medicine that beta-blockers (carvedilol and others) play a role in heart failure management, improving survival, quality of life, cardiac health, and exercise capacity (Packer et al., 1996).The mechanism for this is the blunting of SNS activity, because SNS has multiple harmful effects, including: production of tachycardia and arrhythmias; vasoconstriction with increased afterload; RAAS activation; and myocardial remodeling, apoptotic cell death, and fibrosis.

Uechi et al. (2002) reported that in dogs with experimental mitral valve regurgitation, carvedilol (0.2 mg/kg) decreased heart rate, whereas renal function, arterial blood pressure, and left ventricular contractile function were unaffected. Carvedilol (0.4 mg/kg) decreased heart rate, blood pressure, and renal function. The tachycardic response to isoproterenol was significantly diminished for 36 hours by 0.4 mg/kg carvedilol versus 24 hours with 0.2 mg/kg. The authors determined that carvedilol should be initiated at less than 0.2 mg/kg and titrated up to 0.4 mg/kg for dogs in heart failure.

Because of beta-blockers' negative inotropic effect, they are typically (or always) started prior to heart failure or at least during remission. The dosage is gradually increased until the target (25 mg BID in DCM, or approximately 0.5–1 mg/kg) is reached or the dog can no longer tolerate the drug. If the latter occurs, the dosage is backed off to the previously tolerated dosage and maintained or again carefully increased once stabilization has occurred. Carvedilol and other beta-blockers are typically used in conjunction with other agents used in treating heart failure. Preliminary studies in dogs with MMVD show promise with this agent (Arsenault et al., 2005; Gordon et al., 2005, 2006); however, absorption of carvedilol varies markedly between individuals, making dosage determination difficult (Uechi et al., 2002). Furthermore, the only placebo-controlled, double-blind study of a beta-blocker (bisoprolol) in veterinary medicine failed to show a benefit in slowing the progression to heart failure in dogs with asymptomatic MMVD (Keene et al., 2012). The use of beta-blockers in DCM is still advocated, though their use has not been evaluated in dogs with this affliction.

Ancillary Therapy in Congestive Heart Failure

Diuretics

Diuretics are covered in Chapter 24. The use of potent loop-acting diuretics (furosemide, torsemide, bumetanide) are the mainstay of the management of congestive heart failure in man and animals. Today, in dogs, their use is supplemented with ACEIs and pimobendan in most cases ("triple therapy"). The authors advocate "quadruple therapy," adding spironolactone to any drug regimen, which employs ACEIs. This is because of the phenomenon termed aldosterone breakthrough, described in Section Mineralocorticoid Receptor Blockers, Clinical Use. Furthermore, the authors do not prescribe furosemide as a monotherapy, because of its RAAS-activating properties, similar to that of vasodilators. An ACEI virtually always accompanies the use of furosemide in the authors' clinics.

Patients receiving diuretics should be carefully monitored. Pronounced diuresis can reduce blood volume to the extent that dehydration lowers preload, such that ventricular performance is inadequate. A reduced ventricular filling pressure (preload) is good on the one hand because it reduces wall tension, myocardial oxygen demand, and the propensity for edema formation. Conversely, this reduction in venous return – without concurrent positive inotropic effects – may well lead to reduced cardiac output, which results in reduction in renal perfusion, azotemia, and reduced clearance of certain drugs. Furthermore, inappetance and/or vomiting contribute further to dehydration and electrolyte loss. Hypokalemia is one of the more important concerns in this setting, as potassium levels fall with anorexia, polyuria, excessive diuresis, and emesis. This is, however, counteracted with potassium supplementation, ACEIs, and MRB (spironolactone). Serum electrolyte and renal values (BUN and serum creatinine) should be monitored, along with body weight, state of hydration (skin turgor, packed cell volume, total protein, serum albumin and sodium).

Overview of the Management of Cardiovascular Disease

Type of Heart Disease and Related Hemodynamic Abnormalities

The sympathetic nervous system and RAAS are both activated in heart failure and even before its onset. In virtually all cases, this activation is detrimental to cardiac patients.

In MMVD, contractility is at least partially maintained until the patient reaches terminal stages of illness. But recent studies of pulmonary transit time of blood (time required to traverse the lungs and reach the left atrium) indicate that subtle changes are present much earlier. These dogs have generally not been thought to require inotropic support but, today, pimobendan has been shown to be useful in the management of MMVD-induced congestive heart failure.

In heart failure, preload and afterload are both elevated and should be reduced. Heart rate varies but is usually high and can be reduced with digoxin, for example, and simply by managing heart failure and normalizing the autonomic forces on the cardiovascular system.

Dogs with DCM have similar abnormalities except that contractility is always diminished and often, profoundly so. This requires inotropic support in the emergency room with dobutamine CRI, digoxin IV or PO, or IV or PO pimobendan and chronically with pimobendan PO, with or without digoxin (Figure 21.10).

Cats with HCM suffer diastolic failure and increased preload and afterload, often with elevated heart rate. Afterload increase is not as severe as in eccentrically hypertrophied hearts, as discussed above for MMVD and DCM, because the concentric hypertrophy of HCM (and hypertension) is adaptive in terms of afterload (LaPlace relationship, in which chamber radius increases and wall thickness reduces afterload). Systolic function is thought to be adequate in most cases. Therapy is different with treatment of rapid heart rate, diastolic failure (lusitropic and negative chronotropic drugs), and congestion.

Pressure overload, due most often to systemic hypertension, pulmonary hypertension (heartworm disease, etc), and obstructive disease (SAS, PS, coarctation of the aorta, etc.), also produces heart failure with increased afterload, normal, elevated or decreased preload, and increased heart rate, as in heart failure of other causes.

Severity of Heart Disease

There are numerous classification schemes in veterinary medicine for the categorization of severity of cardiac disease (Atkins and Haagstrom, 2012). Two of these (Figure 21.8), the ISACHC (International Small Animal Cardiac Health Council) and ACVIM (American College of Veterinary Internal Medicine), are most commonly in use today (ISACHC, 1994; Atkins et al., 2009).

The ISACHC classification consists of four categories (Ia, Ib, II, and III), which are schematized in Figure 21.6 and described in Table 21.4. The ACVIM classification of cardiac disease, which was adapted from the American College of Cardiology/American Heart Association classification system, depicted in Figure 21.8, uses an A through D categorization of cardiac disease and does not rely heavily upon exercise tolerance as a criterion, a weakness of previous schemes. It also includes a category (A) for dogs without heart disease but who are at risk (e.g., Cavalier King Charles Spaniels at risk to develop MMVD). Category B includes dogs with mild heart disease, without (B1) and with (B2) cardiomegaly, but without present or historical evidence of congestive heart failure. Category C includes dogs with signs of heart failure, either hospitalized (C1) or treated at home (C2) and is similar to category D, which includes refractory or end-stage heart failure patients, treated in the hospital (D1) or at home (D2). Obviously, this categorization is fluid, with patients able to move back and forth between the stages of heart disease, with decompensation, with disease progression, and with successful treatment.

Choice of Pharmacological Agents, Based on Signs

One can also pick agents based on pathological responses seen in individual patients, for example, congestion, tachycardia, poor systolic function, and arrhythmia. In Tables 21.1 and 21.2 drugs are classified as to the type of abnormality for which they are likely to be indicated, with the suggested dosage.

Antiarrhythmic Agents

Kathryn M. Meurs and Jim E. Riviere

The authors thank HR Adams for the original chapter upon which this is based.

An arrhythmia is typically defined as an abnormality in the rate, regularity, or site of origin of the electrical impulse of the heart, or a disruption in impulse conduction such that the normal sequence of atrial and ventricular activation is changed. In many cases cardiac arrhythmias have no clinical importance, and in some cases are considered normal findings (sinus arrhythmia in the dog). However, arrhythmias that lead to very slow or rapid heart rates or very irregular heart rates can have significant clinical implications, particularly if cardiac disease is present. The decision to treat a cardiac arrhythmia with an antiarrhythmic should be based on many factors including heart rate, type of arrhythmia, presence or absence of clinical signs such as syncope or exercise intolerance, and presence of underlying heart disease. Arrhythmias in the face of underlying heart disease, particularly with myocardial dysfunction (dilated cardiomyopathy, etc.) can be likely to lead to the development of clinical signs, including sudden death. Although there are many antiarrhythmics, only a small number have been well studied and shown to be effective in veterinary medicine and this chapter will concentrate on those. This chapter focuses on the more common antiarrhythmic agents used in veterinary medicine and introduces their principal pharmacodynamic actions on cardiac rate and rhythm.

Rhythmicity of the Heart

Normal cardiac rhythmicity is maintained by (i) dominance of a single pacemaker discharging regularly with the highest frequency, (ii) rapid and uniform conduction through normal routes of impulse conduction, and (iii) long and uniform duration of the action potential and refractory period of cardiac myofibers. In addition, duration of the Purkinje fiber action potential normally outlasts that of the ventricular muscle, thus providing a safety factor preventing reentry and reexcitation of the Purkinje system by the muscle action potential. A disturbance in any of the preceding factors can be arrhythmogenic, for example an inappropriate increase in automaticity of normally latent pacemaker cells, abbreviation of the refractory period, slowing of conduction velocity, or disparate refractory periods of adjacent fibers. Likewise, treatment of arrhythmias with the drugs discussed in this chapter is aimed at correcting these disturbances by altering cardiac pacemaker threshold, sodium, potassium, and/or calcium currents.

Arrhythmias often are associated with: imbalance of the parasympathetic and sympathetic branches of the autonomic nervous system; changes in serum electrolyte concentrations, especially potassium and calcium ions (K^+ and Ca^{++}); hypoxemia; acidosis; changes in concentration of carbon dioxide; excessive stretch of cardiac tissue; mechanical trauma; myocardial disease states such as congestive heart failure and viral myocarditis; numerous drugs; and ischemia and infarction of the heart muscle. Chapters 6, 7, and 8 on the autonomic system and the introduction to cardiac function in Chapter 21 should be consulted for an appropriate background in these areas.

Hemodynamic instability occurring during cardiac arrhythmias results from alterations in heart rate, changing the regularity of heartbeats, and losing atrial assistance in ventricular filling. Electromechanical synchrony of the cardiac chambers is thereby lost, culminating in ineffectual filling and ejection of the ventricles and hemodynamic deterioration of the patient. Antiarrhythmic drugs suppress arrhythmias and help restore hemodynamic stability by altering basic electrophysiological processes in the heart.

Electrophysiological Properties of Cardiac Cells

The classification system for clinically useful antiarrhythmic drugs is based mainly on the predominant pharmacological effects of a drug on the action potential of cardiac cells (Vaughn Williams, 1984; Adams, 1986). Accordingly, a useful understanding of antiarrhythmic drug actions and affiliated nomenclature depends first on

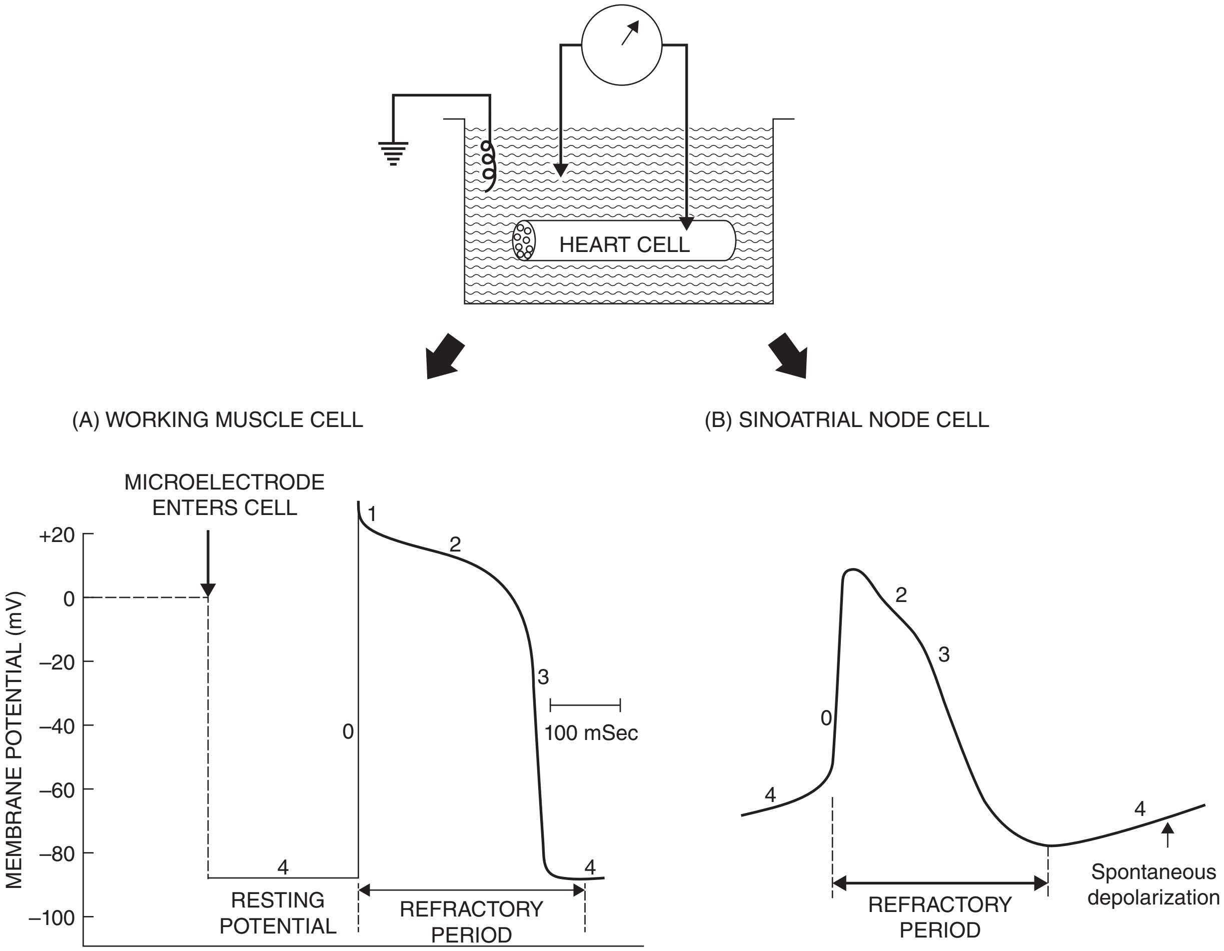

Figure 22.1 Cardiac action potentials recorded from a working myocardial cell (A) and a sinoatrial pacemaker cell (B). The nonautomatic working muscle cell (A) exhibits a constant phase 4 resting potential during diastole, whereas the automatic cell (B) undergoes spontaneous depolarization during phase 4, leading to threshold and spontaneous excitation. The cell is inexcitable or poorly responsive to additional stimuli during much of the action potential, and this refractory period helps prevent premature excitation. See text for further details. Source: Adams, 1986.

a good comprehension of basic bioelectric properties of the heart. An overview of salient features of this topic is outlined here relative to action potentials of cardiac cells and types of cardiac arrhythmogenesis.

Action Potentials of Cardiac Cells

The electrical activity of individual heart muscle cells can be recorded with a microelectrode capable of entering the intracellular space of a single cell, as shown schematically in Figure 22.1. Some of the common terms used to describe the configuration and ionic determinants of cardiac action potential components are defined here (Adams, 1986):

1) Membrane potential is the voltage difference across the cell membrane, that is the difference in electrical voltage between the intracellular and extracellular spaces. By convention, the resting membrane potential is defined as the charge inside the cell relative to the extracellular side, in which case the resting potential is a negative charge. An increase in resting membrane potential would therefore designate a more negative intracellular charge (e.g., an increase from −70 to −90 mV), while a decrease in resting membrane potential would designate a less negative intracellular charge (e.g., a decrease from −70 to −50 mV).
2) Depolarization is the loss or decrease in electronegativity of the intracellular space, for example a decrease in membrane potential from −90 to −50 mV (partial depolarization) or from −90 to 0 mV (complete depolarization).
3) Hyperpolarization is an increase in electronegativity of the intracellular space.
4) Inward current is the change in electrical charge across the cell membrane that results from influx of positively charged ions or, alternatively, from efflux of negatively charged ions.

5) Spontaneous depolarization of automatic cells is a physiological and progressive decrease in resting potential during diastole, leading spontaneously to threshold and automatic firing.
6) Threshold potential is the membrane potential required for excitation of the cell, initiating the action potential and affiliated cellular responses.
7) Phase 0 is the rapid depolarization phase of the action potential of the excited cell, mediated by a rapid inward current carried by Na^+ through fast sodium channels of the cell membrane.
8) Phase 1 is the initial early repolarization phase of the action potential.
9) Phase 2 is the plateau phase of the action potential, mediated in part by a slow inward current carried by Ca^{++} through slow calcium channels of the cell membrane.
10) Phase 3 is the rapid repolarization phase of the action potential, returning membrane potential to the diastolic level.
11) Phase 4 is the membrane potential during diastole; it is constant in working muscle cells but undergoes spontaneous depolarization in cells with automaticity.
12) Refractory period is that early and late interval of the action potential during which excitability of the cell is essentially absent (functional refractory period) or depressed (relative refractory period), respectively.
13) Depressed fast sodium ion (Na^+) responses are slowly rising phase 0 depolarizations due either to premature excitation during the relative refractory period of normal cells or excitation of sick cells with low diastolic potentials; depressed fast Na^+ response action potentials develop cardiac impulses that propagate poorly with reduced conduction velocity.
14) Slow Ca^{++} responses are analogous to the slow inward Ca^{++} current during phase 2; this term is used to describe the very slowly rising phase 0 depolarizations mediated by Ca^{++} when the fast Na^+ channels are inoperative. Slow Ca^{++} action potentials develop cardiac impulses that propagate poorly with extremely slow conduction.

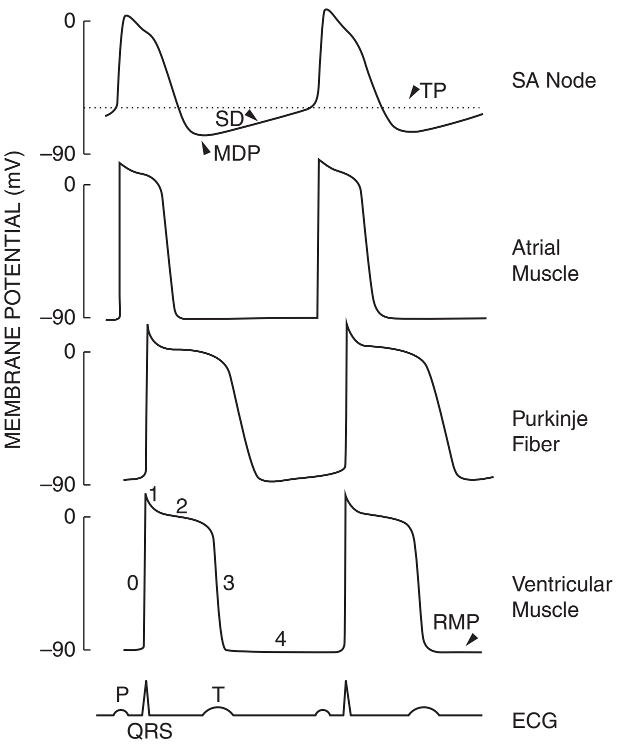

Figure 22.2 Schematic diagrams demonstrating the temporal relationships between transmembrane action potentials recorded from cells of the sinoatrial node (SA), atrial muscle, Purkinje fibers, and ventricular muscle (see text for discussion). Modeled after Trautwein, 1963. Source: Adams, 1986.

When a cardiac cell is stimulated, the electrical potential measured across the cell membrane undergoes a depolarization and repolarization cycle that can be differentiated into five sequential components. These components are referred to as phases 0, 1, 2, 3, and 4 (Figure 22.1). The precise morphology of the 5 phases of the cardiac action potential varies with the anatomic region of the heart. A schematic diagram illustrating the configuration of action potentials derived from sinoatrial (SA) tissue, atrial muscle (AM), Purkinje fibers (PF), and ventricular muscle (VM) is depicted in Figure 22.2 along with corresponding waveforms of the electrocardiogram (ECG). Action potentials of a sinoatrial pacemaker cell (Figure 22.1B) and a typical working heart muscle cell (Figure 22.1A) will be addressed as examples of cardiac tissue with and without normal automaticity, respectively.

Working heart muscle cells: Electrical diastole is designated by phase 4 of the cardiac action potential (Figure 22.1A); this resting membrane potential is steady at about −90 mV. Polarization across the cell membrane is maintained primarily because of the unequal distribution of K^+ inside and outside the cell. The Na^+,K^+-adenosine triphosphatase transport system maintains high intracellular K^+ relative to extracellular K^+, and the cell membrane is selectively permeable to K^+ during phase 4 diastole when compared to other ions such as Na^+ or Ca^{++}. When the cell is stimulated to its particular threshold level, however, the selective permeability characteristics of the cell membrane to K^+ are momentarily lost. Other ions now cross the sarcolemma and produce the typical depolarization–repolarization cycle that comprises the action potential (Figure 22.1).

Phase 0 of the action potential reflects the extremely rapid depolarization spike produced by Na^+ rushing into the cell through specific “fast Na^+ channels” or passageways of the sarcolemma. Phase 0 is terminated as early (phase 1) and delayed (phase 3) repolarization occur, restoring the membrane potential to its resting diastolic level of phase 4 (Figure 22.1). The cell is refractory to additional stimuli during the early and intermediate phase of the action potential cycle; it is only partially responsive if stimulated prior to complete repolarization and return to normal phase 4 diastolic potential.

The phase 2 plateau of the action potential partially represents a brief anomalous delay in restoration of K^+ permeability (Figure 22.1). A critically important component of phase 2 comprises an influx of Ca^{++} through specific “slow Ca^{++} channels” or “slow cation channels” of the cell membrane. This slow inward Ca^{++} current is the mechanism whereby membrane excitation is coupled to activation of the contractile elements of heart muscle cells (Parker and Adams, 1977). The influx of Ca^{++} during phase 2 triggers a release of greater amounts of Ca^{++} from intracellular storage sites, and the increased cytosolic Ca^{++} proportionately activates the contractile machinery of the myocardial cells.

Sinoatrial pacemaker cells: Unlike working myocardial cells, automatic cells do not exhibit a clearly definable resting membrane potential during phase 4. Instead, phase 4 is characterized by a slow spontaneous depolarization to threshold potential (Figure 22.1B), thereby discharging automatically and leading into the more rapid depolarization of phase 0. However, the slope of phase 0 depolarization of SA pacemaker cells is much less than that of working muscle cells (Figures 22.1, 22.2). This distinction may be explained by a component of slow Ca^{++} influx in the genesis of phase 0 depolarization in these types of automatic cells (Adams, 1986). Cells with normal automaticity (i.e., spontaneous phase 4 depolarization) also are found in specialized atrial conduction tracts, the distal region of the AV node, AV valves, and PF.

Classification of Arrhythmogenic Mechanisms

The basic mechanisms involved in genesis of cardiac arrhythmias involve abnormalities of impulse formation (i.e., arrhythmias caused by changes in automaticity), impulse conduction (i.e., arrhythmias caused by reentry phenomena), and a combination of automaticity and reentry (Singh et al., 1980; Binah and Rosen, 1984).

Disturbances in Automaticity

The action potential from the SA node, AM, PF, and VM are shown in Figure 22.2. The five phases of the action potential (0, 1, 2, 3, 4) are numbered in the first complex of VM. Notice spontaneous depolarization (SD), maximal diastolic potential (MDP), and threshold potential (TP) in the automatic cells of SA and PF. The resting membrane potential (RMP) is shown in the nonautomatic cells of the AM and VM. The P wave of the ECG corresponds to depolarization of SA and AM, while the QRS complex and T wave correspond to depolarization and repolarization, respectively, of ventricular cells (Figure 22.2).

Automatic cells of the SA node normally are the dominant pacemaker, reaching threshold first with the resultant propagating impulse exciting all other potential pacemaker cells before they spontaneously attain threshold values (Figure 22.2). If automaticity of the SA node is depressed or the spontaneous firing rate in some other tissue (latent pacemaker) is accelerated, regions of the heart other than the SA node may serve as the pacemaker and initiate ectopic impulses. Examples are shown in Figure 22.3.

Automaticity is enhanced when the slope of phase 4 SD is increased (e.g., from a to b in I of Figure 22.3); this decreases the time required to reach TP, thereby increasing the frequency of spontaneous discharge. The result is an increase in heart rate when the SA pacemaker is involved or emergence of ectopic beats if a normally latent pacemaker is involved. By decreasing the slope of spontaneous depolarization (e.g., from b to a or from a to

Figure 22.4 Schematic representations of potential mechanisms involved in cardiac arrhythmias caused by reentry phenomena. I. Normal. The cardiac impulse (arrows) exits a main bundle branch (MB) of the Purkinje system and enters terminal Purkinje branches A and B. The impulse uniformly and rapidly excites a segment of ventricular muscle (VM) and would be extinguished within the VM due to refractoriness of the cells just excited. II. Normal conduction and unidirectional block. Because of an area of damaged tissue (shaded area) that blocks antegrade conduction in branch A, the impulse traversing branch B and the VM will excite branch A. The impulse will traverse branch A and the area of unidirectional block through a retrograde pathway; however, since it is conducted at a normally fast speed, it will encounter refractory cells (open square) and be extinguished. III. Slow conduction velocity and no block. Although the cardiac impulse may be conducted at an abnormally slow velocity (wavy arrows), the lack of unidirectional conduction block causes the impulse to arrive at refractory cells and extinguish. IV. Slow conduction and unidirectional block. Same as II but the speed of impulse conduction through the area of unidirectional block (wavy arrows), and perhaps through B and VM as well, is so slow that the impulse encounters cells after their refractory period. Thus the impulse can reenter the conduction pathway, thereby establishing perpetual reexcitation. Modeled after Cranefield, 1973; Mason et al., 1973. Source: Adams, 1986.

c in I of Figure 22.3), drugs can depress ectopic foci and restore normal sinus rhythm without affecting MDP or TP. If a drug raises TP to less negative values (e.g., from TP-a to TP-b in II of Figure 22.3), additional time will be required to reach TP, thereby depressing automaticity. By increasing the MDP (e.g., from MDP-a to MDP-b in III of Figure 22.3), a drug can suppress automaticity because additional time would be required before TP is attained.

Disturbances in Impulse Conduction

Arrhythmias caused by disturbances in impulse conduction are thought to be associated with a phenomenon of reentry or circus movement. The concept of reentry is based on very slow conduction velocity, an area of the heart demonstrating unidirectional block of impulse conduction and perhaps an abnormally brief refractory period (Schmidt and Erlanger, 1929; Wit et al., 1972, 1974). This theory holds that a cardiac impulse can travel circuitously around an anatomic loop of fibers in which slowed conduction velocity and brief refractoriness permit the impulse to arrive at cells that are no longer refractory, thereby permitting perpetual reexcitation.

A schematic demonstration of impulse reentry at a junctional region between PF and ventricular muscle is shown in Figure 22.4 (Adams, 1986). Conduction can be significantly slowed by pathological lesions in the heart tissue. Because of slowed conduction, a reentry stimulus can excite tissue that would have otherwise been refractory. Reentry theoretically could be controlled by a drug that either creates bidirectional block or bidirectional conduction through the region of cells causing the unidirectional block; accelerates speed of impulse conduction, thus returning the impulse to the site of reentry when cells are still refractory; prolongs action potential duration of normal cells, thereby extending their refractory period; or exhibits a combination of the above actions.

Other forms of cardiac electrophysiological disturbances, in addition to primary abnormalities of impulse conduction and automaticity, may be important. Examples include abnormal excitability, early/late afterdepolarizations, and triggered electrical activities. These types of abnormalities overlap mechanistically with disturbances of automaticity and impulse conduction. Arrhythmias arising from primary automaticity and conduction abnormalities are adequate for modeling the classes of antiarrhythmic drugs relative to their effects on cardiac action potential characteristics and arrhythmogenesis.

Antiarrhythmic Drugs

Based on mechanisms described above, particularly with respect to ion conduction across cardiac cell membranes, antiarrhythimic drugs can be classified using the traditional Vaughn Williams classification scheme discussed in Section Electrophysiological Properties of Cardiac Cells. This classification is presented in Table 22.1.

Antiarrhythmic drugs are divided into Classes I to IV in this system. Although the clinical importance of this classification scheme has been debated (see Vaughn Williams, 1992), some familiarity with the system is still of value. Some drugs (e.g., digoxin, anticholinergic agents, vagolytics, sympathomimetics) are not classified by this system.

Class I antiarrhythmics block fast sodium channels in the myocardial cell membrane resulting in a decrease in the upstroke velocity of the action potential in atrial and ventricular myocardium and Purkinje cells. By decreasing the upstroke velocity, class I antiarrhythmics slow conduction velocity in normal and abnormal cardiac tissue. Class I drugs also prolong the refractory period and can be effective at abolishing reentrant tachyarrhythmias. Class I agents have variable effects on repolarization. Some of them prolong repolarization while others shorten it or have no effect. Class I agents are also subdivided into classes IA, IB, and IC based on differences in electrophysiological and antiarrhythmic differences (Keefe et al., 1981).

Class IA antiarrhythmics depress conduction in normal and abnormal cardiac tissue and prolong repolarization. Examples used in veterinary medicine are procainamide and quinidine.

Class IB antiarrhythmics have a greater impact on conduction velocity and effective refractory period in abnormal cardiac tissue than in normal tissue. Additionally, their effect is most profound in Purkinje fibers and they have very little effect on the sinus node, atrioventricular node, or cardiac contractility. Examples used in veterinary medicine are lidocaine and mexiletine.

Class IC antiarrhythmics include encainide and flecainide. They are rarely, if ever, used in veterinary medicine. Flecanide was withdrawn from the market after adverse effects were reported in people.

Class II antiarrhythmics are the β-adrenergic receptor blockers. These include atenolol, propranolol, and sotalol. Sotalol is also considered a Class III due to its unique combination of beta-blocking and potassium channel blocking mechanisms.

Table 22.1 Classification of antiarrhythmic drugs based on mechanism of action: Vaughn Williams classification system. Source: Data from Vaughn Williams, 1984.

Class	Drug	Effect on Na$^+$ channels	Effect on K$^+$ channels	Effect on Ca^{++} channels	Effect on action potential
Class Ia	Local anesthetics Procainamide Quinidine	Depresses	Depresses	–	Lengthens action potential Increases refractory period
Class Ib	Local anesthetics Lidocaine Mexiletine	Depresses	Depresses	–	Does not increase refractory period as Class Ia drugs
Class II	β_1-adrenergic blockers Propranolol Atenolol Metoprolol	Depresses	–	Depresses	Suppresses SA, AV node Decreases rate
Class III	Potassium channel blockers Amiodarone Sotalol[a]	–	Depresses	–	Prolongs refractory period Lengthens action potential
Class IV	Calcium-channel blockers Verapamil Diltiazem	–	–	Depresses	Suppresses SA, AV node Decreases rate

[a] Sotalol also has beta-blocking (Class II) properties.

Table 22.2 Dose recommendations for drugs used to treat cardiac arrhythmias

Amiodarone	Dogs: 8–10 mg/kg, orally, twice daily be given for one week and then reduced to 5–10 mg/kg PO once daily thereafter
Atenolol	Dogs: 0.25–1.0 mg/kg, orally, twice daily Cats: 6.25–12.5 mg/dog, orally, twice daily
Atropine sulfate	Dogs and cats: 0.02–0.04 mg/kg, subcutaneously every 4–6 hours, or as a single injection for atropine challenge
Digoxin	Dogs: 0.005 mg/kg, orally, twice daily Cats: 0.008–0.01 mg/kg orally, every 48 hours
Diltiazem	Dogs: 0.5–1.5 mg/kg, orally every 8 hours Cats: 1.75–2.4 mg/kg, orally every 8 hours
Esmolol	0.05–0.1 mg/kg intravenously given slowly
Isoproterenol	1 mg diluted in 500 ml of 5% dextrose of Ringer's solution and infuse intravenously at 0.5–1 ml/min or to effect
Lidocaine	Dogs: 2–4 mg/kg, intravenously Cats: 0.25–0.75 mg/kg, intravenously
Mexiletine	Dogs: 5–7 mg/kg, orally, every 8 hours.
Procainamide	Dogs: 10–30 mg/kg, orally, every 6 hours Cats: 3–8 mg/kg, orally, every 6 hours
Propantheline	0.25–0.5 mg/kg, orally, every 8–12 hours
Quinidine	Horses: 22 mg/kg, via nasogastric tube, every 2 hours until conversion to sinus rhythm, a cumulative dose of 88–132 mg/kg had been administered
Sotalol	Dogs: 1–2 mg/kg, orally, every 12 hours Cats: 1–2 mg/kg, orally, every 12 hours
Terbutaline	Dogs: 1.25–5 mg/dog, orally, every 8 hours Cats: 0.1–0.2 mg/kg, orally, every 12 hours

Class III antiarrhythmics prolong the action potential and increase the refractory period. Examples used in veterinary medicine are amiodarone and sotalol.

Class IV antiarrhythmics are the calcium channel blockers. The most common example is diltiazem.

A practical approach to consider which antiarrhythmic to administer is to begin by diagnosing the rhythm abnormality and selecting a drug based on the underlying heart rate or arrhythmia. Initial therapy should be directed at correcting specific etiologies; for example if serum electrolyte abnormalities are responsible, obviously these should be corrected before an antiarrhythmic drug is introduced. Dose recommendations are provided in Table 22.2.

Bradyarrhythmias

Bradyarrhythmias are arrhythmias with heart rates that are below the normal range. Sinus bradycardia may be due to systemic issues including hypothermia, hypothyroidism, and issues that lead to high vagal tone. Sick sinus syndrome and atrioventricular block are bradyarrhythmias that are typically a result of sinus node or atrioventricular node issues. These arrhythmias may be responsive to drugs that can increase heart rate, termed positive chronotropic drugs. However, if they are not responsive to medical therapy, a pacemaker may be needed.

Two mechanisms for increasing heart rate are to decrease vagal tone (vagolytics) or increase sympathetic tone by stimulation of the β-adrenergic receptors in the sinus or atrioventricular nodes (sympathomimetic adrenergic drugs).

Vagolytics such as atropine and propantheline bromide are commonly used to treat bradyarrhythmias that are a result of high vagal tone. These drugs were introduced in Chapter 8. Atropine is frequently used acutely in anesthetized patients in which a bradycardia is observed. It can also be used to determine how responsive a bradyarrhythmia might be to a vagolytic treatment by doing an atropine challenge. In these cases, atropine may be given at a dose of at 0.4 mg/kg subcutaneously and the heart rate rechecked in 30 minutes. An increase in heart rate after the atropine challenge indicates that the arrhythmia may have a component of high vagal tone and may be responsive to an oral vagolytic or sympathomimetic.

Propantheline Bromide

Mechanism of action and pharmacology: Propantheline bromide is an antimuscarinic agent with similar actions to atropine, but it exists in an oral formulation and may be appropriate for chronic use. Propantheline is primarily metabolized in the gastrointestinal tract and liver and is not completely absorbed after oral administration. There is likely a variable rate of absorption among dogs. Because of the lack of specific information regarding oral absorption and onset of action, it is recommended that each case be closely monitored and doses adjusted as needed.

Side effects, adverse effects, and tolerance: As a vagolytic, propantheline could be expected to lead to sinus tachycardia, increased salivation, and vomiting.

Clinical use: In small animal medicine, propantheline can be used an oral treatment for atropine challenge responsive bradyarrhythmias including sick sinus syndrome and possibly second-degree atrioventricular block. However, it may not be as effective as the sympathomimetics described below and is not used as commonly.

Clinical monitoring: Propantheline is used most commonly to increase heart rate in dogs with bradycardias that are responsive to atropine, and response to therapy is variable (Rishniw and Thomas, 2000). Heart rate and rhythm should be monitored with electrocardiography to monitor for a response to therapy. Owners should be advised of possible clinical signs including increased salivation and vomiting.

Isoproterenol

Mechanism of action and pharmacology: Isoproterenol is a sympathomimetic, introduced in Chapter 7, that increases heart rate by stimulating both the β_1 and β_2 receptors in the sinus and atrioventricular node. Although an oral form is available, isoproterenol is most commonly used intravenously for short-term treatment. The intravenous form is very rapid acting and the effect is decreased rapidly after discontinuation.

Side effects, adverse effects, and tolerance: As a stimulant of the β receptors, isoproterenol can lead to tachycardia, increased contractility, hypotension, and arrhythmias, particularly if underlying heart disease is present. However, the side effects will be rapidly reduced after decreasing the dose or by discontinuing the infusion. Although chronic administration is unlikely, long-term exposure can induce congestive heart failure in dogs.

Clinical use: Isoproterenol can be given intravenously for patients with emergency bradycardias (atrioventricular block, sick sinus syndrome) while waiting for surgical intervention with a pacemaker.

Clinical monitoring: Isoproterenol can lead to hypotension as well as cardiac arrhythmias; therefore, blood pressure monitoring and continuous electrocardiography should be performed for the duration of infusion. This also helps determine if the dose should be adjusted for an improved heart rate response.

Tachyarrhythmias

Sinus Tachycardia

Sinus tachycardia is typically a response to low blood pressure, pain, sepsis, fever, or low cardiac output. Note that many of these are systemic issues rather than a primary cardiac issue and do not require specific antiarrhythmic drug treatment. Sinus tachycardia can also be associated with congestive heart failure as a response to low cardiac output. Because sinus tachycardia is most commonly a sign of underlying systemic or cardiac disease, the primary cause should be addressed by correcting underlying problems. Treatments include administration of fluids if needed to correct blood pressure, considering pain relief, and if the sinus tachycardia is secondary to low cardiac output and heart disease, treating the heart disease with cardiac drugs including pimobenden and angiotensin-converting enzyme inhibitors (ACE-inhibitors) as indicated and fully discussed in Chapter 21.

Supraventricular Tachyarrhythmias

In small animals, supraventricular tachyarrhythmias are usually caused by primary cardiac disease and secondary atrial enlargement, and are not likely to completely resolve with antiarrhythmic drug treatment. Therefore, treatment is directed at slowing the rapid conduction through the atrioventricular node with one of three options: digitalis, a calcium channel blocker or a β-adrenergic receptor blocker.

Digoxin

Mechanism of action and pharmacology: Digoxin's mechanism as an antiarrhythmic is predominantly due to a parasympathetic effect (vagomimetic effect) on the sinus node, atrioventricular node and atrial tissue. This class of drugs has been extensively discussed in Chapter 21. This impact slows conduction through the atrioventricular node and increases vagal tone to the ventricle (Ettinger, 2010). The pharmacokinetics have been described in several veterinary species, which has defined the distribution, elimination, and recommendations for dosage regimens. The dose of digoxin is based on the animal's lean body weight because it is preferentially distributed to muscle instead of fat. It is metabolized by the liver and excreted by the kidney. Dose adjustments based on clinical monitoring should be done in patients with both cardiac and kidney disease.

Adverse effects, adverse effects, and tolerance: The most common clinical signs are gastrointestinal and include nausea, loss of appetite, vomiting, and diarrhea. Cardiac arrhythmias may also develop including atrioventricular block, ventricular premature complexes, and tachycardia. Hypokalemia can exacerbate the toxicity.

Clinical use: The most common antiarrhythmic use of digoxin is for the treatment of supraventricular tachycardia by slowing conduction through the atrioventricular node and slowing the ventricular response rate. However, in many cases, the reduction in heart rate is not significant to have clinical importance and it may be necessary to add on a Class IV (calcium channel blocker), typically diltiazem, or a Class II (β-adrenergic receptor blocker), typically atenolol (Gelzer et al., 2009). In cases with congestive heart failure or significant myocardial dysfunction, it may be reasonable to first give digoxin to decrease the heart rate since it is also a positive inotrope (diltiazem and atenolol are negative inotropes). Once the heart disease is more stable, atenolol or diltiazem may be added on to improve the heart rate reduction and to obtain a target rate closer to 150 beats per minute.

Clinical monitoring: As mentioned in Chapter 21, there is tremendous patient variability for digoxin toxicity and individual patient factors including obesity, ascites, hypoalbunimea, renal disease, and thyroid status can all be involved (Merrett, 2000). Due to the difficulty in predicting digoxin toxicity, it is prudent to measure serum levels 10–14 days after starting digoxin. Samples should ideally be drawn 6–8 hours postadministration. Most clinicians aim for a target range of 0.8 – 1.2 ng/ml for dogs (Trepanier, 2013), although some dogs may show clinical signs of toxicity even within the therapeutic range and others will not act at all toxic even when their level is above this range. There is anecdotal evidence that management of atrial fibrillation requires higher concentrations than for treatment of heart failure, but this has not been confirmed through clinical trials. If signs of toxicity develop, digoxin should be completely discontinued for 48 hours before restarting at half of the previous dose. Cats can be particularly sensitive to digoxin and should be started at the low end of the dose. Fortunately, cats infrequently develop significant supraventricular tachycardia and the use of digoxin for this purpose in the cat is relatively uncommon. Digoxin is also used in horses but most commonly in combination with quinidine for the treatment of atrial fibrillation. Since individual animals have such variation in the likelihood of the development of toxicity, owners should always be advised of possible clinical signs of toxicity so that they can watch them if they develop before serum levels are measured.

Calcium Channel Blockers

Mechanism of action and pharmacology: In veterinary medicine, both verapamil and diltiazem are calcium channel blockers (Class IV agents, Table 22.1) that have been used for their antiarrhythmic activity. However, diltiazem is used more commonly due to a much lower level of effects. Diltiazem is an L-type calcium channel blocker that works by inhibiting the transmembrane influx of extracellular calcium ions into myocardial cells and vascular smooth muscle without altering serum calcium concentrations (Tidholm, 2010). It slows the sinus node depolarization rate as well as atrioventricular node conduction and depolarization rate. It can have a use-dependent rate and therefore has a more profound ability to decrease the ventricular rate with faster heart rates (Pariaut, 2014).

Side effects, adverse effects, and tolerance: Adverse effects of diltiazem are fairly rare in the dog although bradycardia and atrioventricular block could develop. In cats, gastrointestinal signs, including vomiting and anorexia have been observed, but are fairly uncommon. Diltiazem is a negative inotrope by virtue of the Ca^{++} channel blockade. This action could potentially produce cardiac decompensation if administered to animals with significant myocardial dysfunction. However, this is uncommon.

Clinical use: As an antiarrhythmic, the most commonly used calcium channel blocker for veterinary medicine is diltiazem and it is used most commonly to treat supraventricular tachycardia.

Clinical monitoring: Diltiazem is used primarily to slow the ventricular response rate in supraventricular tachycardia so assessment of heart rate is important to determine if the effective dose is being provided. An in-house electrocardiogram for 3–5 minutes is an inexpensive way to occasionally monitor the heart rate and rhythm, but it may not give an accurate representation of the resting heart rate when the animal is relaxed in a home setting. Therefore, many clinicians prefer to monitor heart rate control with a 24-hour Holter monitor after 10–14 days of treatment.

Beta-Adrenergic Receptor Blockers

Beta-adrenergic receptor blockers (beta-blocker, Class II agents, Table 22.1) are predominantly used as an antiarrhythmic for supraventricular tachycardias, although they may be helpful in some cases for treating ventricular tachyarrhythmias particularly if sympathetic tone is involved. Additionally, sotalol, a combination beta-blocker and potassium channel blocker (Class II and Class III agent, Table 22.1) is a very effective ventricular antiarrhythmic.

For treatment of supraventricular arrhythmias, beta-blockers are most commonly used to alter the electrophysiological properties of the atrioventricular node and to decrease the ventricular response rate. Additionally they can prolong the time that the atrioventricular junction is refractory to further stimulation, which is particularly helpful to disrupt reentrant circuits that use the atrioventricular node as part of the reentry circuit.

Beta-blockers are classified according to the β-adrenergic receptors that they block (see Chapters 6 and 7). Beta-blockers can selectively block the β_1 receptors, or nonselectively block both β_1 and β_2 receptors, or partially block β_1 receptors. The most commonly used selective beta-blocker for supraventricular tachycardia in veterinary medicine is atenolol. Esmolol, also a selective β_1-blocker, has a very short half-life and can be given intravenously to disrupt very rapid supraventricular tachycardias. Sotalol is a combination beta-blocker and potassium channel blocker that can be used effectively for both supraventricular and ventricular tachycardias. A few other beta-blockers are used in veterinary medicine for their negative inotropic effect or for cardioprotective strategies, including propranolol, metoprolol, and carvedilol. These are much less commonly used as antiarrhythmics.

Atenolol

Pharmacology: Atenolol is a specific β1-adrenergic blocking drug.

Side effects, adverse effects, and tolerance: Very high doses of atenolol can produce bradycardia although this is uncommonly observed. Due to its β-receptor blocking effects, atenolol is a negative inotrope and could exacerbate heart failure or myocardial dysfunction in patients with low cardiac reserve. It should be administered cautiously when these issues are present.

Clinical use: Atenolol is most commonly used in conjunction with digoxin to slow the heart rate in patients with atrial fibrillation or other rapid supraventricular tachycardias.

Clinical monitoring: As for diltiazem, ideally a Holter monitor would be used to monitor heart rate control after 10–14 days of treatment.

Esmolol

Pharmacology: Esmolol is an ultrashort-acting (half-life <10 minutes) β_1 blocker used commonly for intravenous administration. Steady state β-blockade is produced within 10–20 minutes after starting intravenous administration of esmolol in dogs. After discontinuation of drug administration, no detectable β-blockade is apparent at 20 minutes postinfusion, regardless of the dose administered.

Side effects, adverse effects, and tolerance: Esmolol can cause sinus bradycardia and decrease myocardial function so it should be used with care in patients with congestive heart failure or underlying systolic function. Additionally, it can sometimes stop the tachyarrhythmia quite abruptly leading to sinus arrest so careful monitoring is warranted while infusing.

Clinical use: As an antiarrhythmic, esmolol is primarily used for acute termination of very rapid supraventricular tachycardias.

Clinical monitoring: A continuous electrocardiogram should be monitored while infusing esmolol to observe for the onset of bradycardia or acute discontinuation of the supraventricular arrhythmia. An advantage of esmolol is that the half-life is very short; therefore, if adverse effects are observed, termination of the infusion will ordinarily result in attenuation of effects quickly. In cases of the abrupt occurrence of sinus arrest, sometimes epinephrine is needed to increase the sinus rate.

Sotalol

Mechanism of action and pharmacology: Sotalol is a nonselective beta-blocker and potassium channel blocker (Class II and Class III; Table 22.1).

Side effects, adverse effects, and tolerance: As for any beta-blocker, the heart rate is expected to decrease with sotalol administration. It also prolongs the AV nodal refractory period and the PR interval because of its beta-blocking effect and can sometimes produce mild atrioventricular block. Because it is a beta-blocker, a decrease in myocardial contractility is expected but it should not produce adverse effects in patients with normal heart function. Additionally, as an antiarrhythmic, sotalol does have a potential to be proarrhythmic although this would appear to be fairly uncommon in comparison to some of the older antiarrhythmics such as procainamide.

Clinical use: As a beta-blocker and potassium channel blocker sotalol is effective for both supraventricular and ventricular tachyarrhythmias and can be particularly helpful for patients with both types of arrhythmias.

Clinical monitoring: Ideally a 24-hour Holter monitor should be performed after 10–14 days of treatment to evaluate the efficacy and the heart rate control.

Ventricular Tachycardia

The efficacy of an antiarrhythmic on a ventricular tachyarrhythmia likely depends on the mechanism of the arrhythmia. The most likely possible mechanisms for ventricular arrhythmia development include reentry, and triggered and abnormal automaticity. Unfortunately, the mechanism of the arrhythmia cannot be detected from the clinical aspects of a case and it is not possible to select the antiarrhythmic based on a known mechanism for arrhythmia development. Instead, the antiarrhythmic is typically selected from a small number of available antiarrhythmics with tolerable safety profile.

The goals of treating a ventricular tachyarrhythmia are to decrease the number of abnormal ventricular complexes, as well as the complexity of the arrhythmia, and to hopefully reduce clinical signs (generally syncope) and the risk of sudden cardiac death. The most commonly used ventricular antiarrhythmics (sotalol and mexiletine) are effective at reducing the number of ventricular premature complexes (VPCs) and the complexity of the arrhythmia, and some veterinary cardiologists believe that they do decrease episodes of syncope. However, the overall effect of the antiarrhythmics on preventing sudden cardiac death in veterinary medicine is undetermined.

Procainamide

Mechanism of action and pharmacology: Procainamide is a Class IA antiarrhythmic that decreases myocardial excitability, slows conduction velocity, and prolongs refractory period in the atria, ventricles and His-Purkinje system. In humans and other animals, when procainamide is metabolized, an active metabolite is formed, *N*-acetylprocainamide (NAPA), which has moderate antiarrhythmic effects (Class III antiarrhythmic effects). Dogs are the only mammals that do not produce this metabolite (Papich et al., 1986), which may explain why higher concentrations and higher doses are needed to control arrhythmias compared to people.

Side effects, adverse effects, and tolerance: Procainamide can be proarrhythmic. In one canine study, 50% of the dogs showed an increase in VPC number after 14–21 days of oral procainamide (Meurs, 2002). Procainamide can also have mild negative inotropic effects, but this is rarely a clinically significant issue unless the patient has underlying myocardial disease. Other adverse effects can include gastrointestinal signs (vomiting, diarrhea), widening of QRS and QT intervals, and hypotension. Adverse effects are usually dose related. An important adverse effect in people from procainamide is drug-induced lupus. People who are slow metabolizers have a higher incidence of this adverse effect, but it has not been reported in dogs. People are also susceptible to arrhythmias related to long Q-T syndromes, which can be serious (Class III antiarrhythmic effect). Because of these problems in people, the drug is rarely, if ever, used in human medicine and most dosage forms are no longer available.

Clinical use: Procainamide has been used for treatment of ventricular and supraventricular arrhythmias. However, because of serious adverse effects noted above, particularly the proarrhythmia aspect, it is rarely the first choice for either. It can be used to treat very rapid ventricular arrhythmias in which an intravenous route for dosing may be needed, but it should be injected slowly over 10–20 minutes and has a wide dosing range. Therefore, it is usually the second choice for acute treatment of ventricular tachyarrhythmia in comparison to lidocaine (see Section Lidocaine).

Clinical monitoring: Due to the proarrhythmic effect that can be observed, a continuous electrocardiogram should be monitored during infusion of the intravenous form. If the oral formulation is used, a 24-hour Holter monitor should be evaluated after 14–21 days of therapy to make sure that the arrhythmia has improved and not become worse.

Quinidine

Quinidine is now rarely used in small animals. Its primary use in veterinary medicine at this time is for management of atrial fibrillation in the horse.

Mechanism of action and pharmacology: Quinidine is a Class IA antiarrhythmic that decreases the rate of phase 0 depolarization of cardiac cells and also decreases the slope of spontaneous depolarization of Purkinje fibers. Its main benefit for atrial fibrillation is its ability to prolong the effective refractory period of atrial muscle but it also can prolong the effective refractory period of ventricular muscle with relatively less effect on the refractory period of normal pacemaker cells. The capability of quinidine to directly prolong the refractory period of atrial fibers is thought to account for its ability to convert atrial fibrillation to sinus rhythm. However, quinidine also has an atropine-like activity (vagolytic) that leads to improved AV conduction. Therefore, a complication of using quinidine for treating supraventricular tachyarrhythmias is that it can actually result in an increase in ventricular rate before the atrial dysrhythmia itself is controlled. This characteristic seems to be particularly prevalent when quinidine is administered by the intravenous route.

Side effects, adverse effects, and tolerance: The most common side effects of quinidine are cardiovascular and gastrointestinal and can be quite dramatic requiring careful monitoring of horses being treated with the drug. Cardiovascular effects include hypotension, prolongation of the QRS and QT complex, arrhythmias, and decreased contractility. Horses with concurrent systolic dysfunction could advance into congestive heart failure because of effects on myocardial function. Tachyarrhythmias, including both supraventricular and ventricular, and subsequent sudden death have been reported. Quinidine can also lead to urticarial wheals, colic like symptoms, inflammation of the nasal mucosa with respiratory difficulty, and laminitis (Detweiler, 1977). Quinidine is also a well-known inhibitor of P-glycoprotein, a membrane pump that can be important for clearance of some drugs (Fromm et al., 1999). This interaction is attributed to causing the increased (and potentially toxic) concentrations of digoxin when the drugs are administered concurrently. Because of the well-known effects of quinidine on P-glycoprotein, this drug is often considered as a probe to investigate P-glycoprotein-mediated drug interactions.

Clinical use: The primary use of quinidine is for the treatment of atrial fibrillation in horses (Reef et al., 1995). The use in small animals has declined because of lack of oral dosage forms and adverse effects. When used in horses, quinidine is typically administered via nasogastric tube every 2 hours until conversion to sinus rhythm or a cumulative dose of 88–132 mg/kg, or adverse or toxic effects from the drug. Because of the risk of tachyarrhythmias, increased atrioventricular conduction and decreased contractility, digoxin should be administered before quinidine treatment if the horse has evidence of systolic dysfunction, was prone to tachycardia or had a previous history of sustained tachycardia. Digoxin will help slow atrioventricular conduction and control the ventricular rate in atrial fibrillation and flutter. However, care should be exercised in the concomitant use of digoxin and quinidine, since the latter may substantially increase the plasma concentration of the former (Leahey et al., 1978; Fromm et al., 1999). A study has suggested that addition of digoxin to quinidine might improve the atrial fibrillation conversion rate (Lotstra et al., 2015).

Clinical monitoring: The significant clinical signs that can be observed with quinidine lead to a the need for significant monitoring while treating, including blood pressure monitoring, electrocardiography for evidence of arrhythmias or prolongation of the QRS and QT complexes, and measurement of quinidine levels. The detection of significant adverse effects should lead to discontinuation of quinidine and measurement of a plasma quinidine level.

Lidocaine

Lidocaine is perhaps the most common agent administered IV for acute treatment of ventricular arrhythmias.

Mechanism of action and pharmacology: Lidocaine is a Class IB antiarrhythmic that acts to decrease the rate of ventricular firing, action potential duration and absolute refractory period, and increasing relative refractory period. It has very little effect on atrioventricular node or His-Purkinje conduction. It has a very rapid onset (within a few minutes) when given as an intravenous bolus and can last for more than 10 minutes. However, if continued use is indicated, a continuous rate infusion (CRI) can be provided. To avoid the time to reach steady-state concentrations in dogs, a loading dose may be administered (2–4 mg/kg IV) followed by a CRI of 25–75 μg/kg per minute IV. Lidocaine has a very high first-pass metabolism in the liver and is not effective if administered orally. Mexiletine (discussed in Section Mexiletine) is chemically modified to avoid the first-pass effects and can be administered orally.

Side effects, adverse effects, and tolerance: The side effects of lidocaine are most frequently neurological including depression, seizures, and vomiting, particularly at the high end of the dose. Since it is so short acting, the signs usually resolve once the CRI is discontinued. If clinical signs are severe, the infusion should be decreased or discontinued. If seizures develop they can generally be controlled with diazepam but they usually resolve as soon as the lidocaine infusion rate is decreased or discontinued. If further treatment is indicated, it may be worth considering a change to a different intravenous ventricular antiarrhythmic like procainamide. Cats tend to be much more sensitive to the neurological and cardiac effects of lidocaine and its use in this species is not recommended by cardiologists.

Clinical use: Lidocaine is most useful for acutely converting a ventricular arrhythmia to sinus rhythm. Lidocaine is most effective when the serum potassium level of the patient is at the high normal range; therefore, potassium supplementation should be considered for optimal efficacy if the patient is hypokalemic. However, lidocaine is not useful for chronic therapy since it cannot be given orally, so if continued antiarrhythmics are needed, it is necessary to change to an oral antiarrhythmic such as sotalol or mexiletine. Because of the rapid onset and offset of action of intravenous lidocaine, the first and second dose of the oral antiarrhythmic is often given before discontinuing the intravenous lidocaine. This allows the new antiarrhythmic to begin to develop effective serum levels before removing the lidocaine.

If a ventricular arrhythmia is poorly responsive to lidocaine, consider reevaluation of the serum potassium level and possible supplementation since potassium levels should be in the high normal range for maximum lidocaine effect. Additionally, sometimes decreased levels of myocardial magnesium may be associated with ventricular arrhythmias and magnesium supplementation may be helpful. Finally, since the efficacy of an antiarrhythmic is often dependent on the underlying mechanism of the arrhythmia (which is rarely known), it is sometimes prudent to switch to a different antiarrhythmic. If the response to lidocaine appears to be insufficient and the potassium level is appropriate, it may be reasonable to consider switching to intravenous procainamide.

Another clinical use of lidocaine is to treat pain syndromes and intestinal postoperative ileus in horses (Malone et al., 2006). The effect is likely not via a prokinetic action on the intestine (Milligan, et al., 2007), but by improving repair of the intestinal mucosa in the postoperative period. Lidocaine is also included in clinical infusion protocols, often combined with other agents such as ketamine and morphine (“MLK”) to treat perioperative pain.

Clinical monitoring: A continuous electrocardiogram should be observed while treating with lidocaine to observe for efficacy. Additionally, the patient should be observed for neurological signs.

Mexiletine

Mechanism of action and pharmacology: Mexiletine is similar to lidocaine in that it inhibits the inward sodium current and reduces the rate of rise of the action potential. Mexiletine can also interrupt reentry circuits by slowing conduction and depressing membrane responsiveness.

Side effects, adverse effects, and tolerance: Mexilitine can cause similar neurological effects to lidocaine including nausea, anorexia, vomiting, and depression, as well as bradycardia. As with all antiarrhythmics, it can be proarrhythmic but this appears to be quite uncommon. However, overall mexiletine is actually very safe has become a popular and effective ventricular antiarrhythmic. The most common adverse effect noted in animals is gastrointestinal with some mild loss of appetite or vomiting. Cardiologists have observed that giving mexiletine with at least a small meal may alleviate these gastrointestinal effects.

Clinical use: Mexiletine is most useful for chronic management of ventricular arrhythmias and appears to be able to reduce both the number of ventricular premature beats as well as the complexity (runs, bigeminy, etc.) of the arrhythmia. However, in cases that are refractory to management with mexiletine, success is frequently achieved by combination therapy with sotalol. Since mexiletine and sotalol are in different classes of antiarrhythmics they have different mechanisms of action and appear to have a synergistic effect when given together. One of the adverse electrophysiological effects of sotalol is increased action potential duration (Class III effect) and mexiletine may also counteract the adverse effects of sotalol on the action potential duration.

Because it suppresses sodium channels in activated neurons, another use of mexiletine in people – but not reported in animals – is its use for treating chronic pain. It is used to treat pain caused by diabetic neuropathy and nerve injury and much lower doses than the antiarrhythmic dose.

Clinical monitoring: Ideally a 24-hour Holter monitor should be performed after 10–14 days of treatment to monitor for efficacy. The goal would be to have at least an 85% reduction in VPC number and a reduction in complexity (for example, from runs to singles).

Amiodarone

Mechanism of action and pharmacology: Amiodarone is classified as a Class III antiarrhythmic agent (Table 22.1) that prolongs action potential duration and refractory period. It has a high degree of side effects and is typically reserved for use in very difficult to treat arrhythmias that are not responsive to sotalol, mexiletine, or the combination of both. Amiodarone can be used to treat both supraventricular and ventricular tachycardias.

Amiodarone is a complex antiarrhythmic that shows properties of all four of the main classes. It is structurally related to levothyroxine and has high iodine content. It is metabolized to desethylamiodarone in the dog. Desethylamiodarone has important antiarrhythmic effects because of its ability to block fast sodium channels. Amiodarone has unusual pharmacokinetics. After repeated administration, the drug has a long half-life of 3.2 days in the dog. It is very lipophilic and accumulates in adipose tissue up to 300 times the plasma concentration. Once drug administration is discontinued, amiodarone is cleared rapidly from all tissues except adipose tissue. Although it can be given intravenously as well as orally, it is most commonly given orally.

Side effects, adverse effects, and tolerance: Amiodarone can have a number of adverse effects including anorexia and vomiting. Additionally, quite severe cases of neutropenia, thrombocytopenia, and hepatotoxicity have been observed. In many cases, the adverse effects are thought to be dose related and reversible if discontinued early enough, although some deaths have been reported (Kraus et al., 2009). There are reports that Doberman dogs are more prone to adverse effects than other breeds. Alternatively, the adverse effects in dogs may be caused by the drug vehicle, Polysorbate 80, which is known to elicit allergic-like adverse reactions in dogs caused by histamine release. Pretreatment with antihistamines can be considered if these adverse effects are observed.

Clinical use: Amiodarone has been used to treat both atrial fibrillation and ventricular tachyarrhythmias in the dog (Saunders et al., 2006) and atrial fibrillation in horses. However, due to the frequency of significant adverse effects, including hepatotoxicity and neutropenia, which require careful monitoring, amiodarone is often withheld for the treatment of refractory arrhythmias that are not responsive to the safer antiarrhythmics, including sotalol or mexiletine, alone or in combination.

Clinical monitoring: Careful monitoring of liver enzymes, white blood cell and platelet counts should be done on a regular basis with consideration of discontinuing amiodarone if the liver enzymes are elevated or cell counts are down. Amiodarone serum level measurement is available, although how to use this to guide therapy in veterinary medicine is not yet well understood. A 24-hour Holter monitor should be performed after 10–14 days of treatment to monitor for efficacy.

Sotalol

Mechanism of action and pharmacology: As described above in Section Supraventricular Tachyarrhythmias, sotalol is a nonselective, weak beta-blocker and potassium channel blocker (Class II and III; Table 22.1). It is also very effective for treating ventricular tachyarrhythmias.

Side effects, adverse effects, and tolerance: Sotalol can prolong the AV nodal refractory period and the PR interval and can sometimes lead to mild atrioventricular block. Because it is a β-blocker, a decrease in myocardial contractility is expected but is uncommon, particularly in patients with normal heart function. Additionally, as an antiarrhythmic, sotalol does have a potential to be proarrhythmic although this is fairly uncommon.

Clinical use: For ventricular arrhythmias it has been shown to decrease the number and complexity of ventricular arrhythmias as well as syncope (Meurs, 2002). It is a very effective and safe ventricular antiarrhythmic for veterinary medicine. It is frequently given in conjunction with mexiletine for refractory arrhythmias.

Clinical monitoring: Ideally a 24-hour Holter monitor should be performed after 10–14 days of treatment to monitor for efficacy.

Conclusion

Although in many cases cardiac arrhythmias have no clinical importance and do not require treatment, cardiac arrhythmias can lead to the development of significant clinical signs including sudden cardiac death and do sometimes require antiarrhythmic therapy. The decision to treat a cardiac arrhythmia with an antiarrhythmic should be based on many factors including heart rate, type of arrhythmia, presence or absence of clinical signs such as syncope or exercise intolerance, and presence of underlying heart disease. Although there are many antiarrhythmics, only a small number have been well studied and shown to be effective and safe in veterinary medicine. Selection of the antiarrhythmic should be based on the type of arrhythmia, risk of clinical signs, and side effects of the available antiarrhythmics. The perfect antiarrhythmic does not exist and it may be necessary to try more than one, and to consider combinations when appropriate.

Principles of Acid–Base Balance: Fluid and Electrolyte Therapy, Blood Substitutes

Maya M. Scott-Garrard, Melisa Rosenthal, and Deborah T. Kochevar

Composition and Distribution of Body Fluids

Units of Measure

The units of measure commonly utilized in discussion of fluid balance are presented in Table 23.1. Ions or electrolytes combine according to valence (charge) rather than molecular weight. Hence in the case of univalent ions, 1 mM = 1 mEq. One mM of a divalent ion provides 2 mEq. By expressing most electrolyte concentrations in milliequivalents per liter (mEq/l), and comparing the concentration of cations to anions in the body, it becomes clear that electroneutrality exists. Although extracellular cations are often more completely documented in the course of clinical investigations, anions, particularly chloride and bicarbonate, are the electrical counterbalance. Some electrolytes are measured in millimoles per liter (mM/l) because they exist in variable states of protein binding or valence. An example is total calcium, because protein binding confounds any simple assessment of ionized fraction. Phosphorus exists in variable proportions of phosphate and monohydrogen and dihydrogen phosphate, so no valence can be assigned and calculation of milliequivalence is therefore inaccurate. Since mEq/l are the most common and informative unit of comparison for most electrolytes, conversion formulas are also provided in Table 23.1.

Solutes exert an osmotic effect in solution that is dependent only on the number of particles in solution, not on molecular weight or valence. Hence for nondissociable substances, 1 osmole contains 1 mole of substance. If a substance dissociates in solution, the number of osmoles is increased according to the number of particles generated per mole of dissociated substance. For example, each mmol of a completely dissociated NaCl solution yields 2 mOsm. Osmolarity refers to the number of osmoles per liter, and osmolality indicates the number of osmoles per kilogram of solvent (Rose, 1989). In physiological systems the difference between these two is usually small. The concept of osmolality explains why solutions of diverse chemical and electrical composition (e.g., 5% dextrose, 0.9% NaCl, and 1.3% sodium bicarbonate) can all be considered isotonic. For mammals, isotonic solutions equal approximately 300 mOsm.

Body Fluid Compartments

Semipermeable membranes separate most body compartments, allowing the free passage of water and selected solutes. The effective osmolality, or tonicity, of a solution is related to the ability of a solute to attract water and to sustain an increase in osmotic pressure as a result of water movement. For example, two substances with equal ability to attract water down a concentration gradient and across a semipermeable membrane may have very different effects on osmotic pressure, depending upon the movement of the substance itself through the semipermeable membrane. While the measured osmolality of a solution includes all osmoles, whether effective or ineffective, tonicity of a solution relates only to effective osmolality. For example, a solution containing 300 mOsm of nonpenetrating NaCl and 100 mOsm of urea, which can cross plasma membranes, would have a total osmolarity of 400 mOsm and would be hyperosmotic. However, if one put red blood cells in this solution, they would not shrink or swell, because the urea would diffuse into the cells and reach equilibrium inside and outside the cells. Thus, both extracellular and intracellular solutions would have the same osmolarity. There would be no difference in the water concentration across the membrane and no change in cell volume. The solution is therefore considered isotonic.

Ultimately all fluids within the body are in dynamic equilibrium, but it is helpful during fluid therapy to consider body water as existing in several compartments since critical fluid shifts can and do occur. Determination of the volumes of these compartments is problematic, as can be deduced from the large number of different methods that have been used to estimate these volumes (Kohn and DiBartola, 1992). The most common method for assessment of volume in body fluid compartments

Table 23.1 Units of measure and conversions commonly used in fluid therapy

Term	Abbreviation	Description and conversion
Molecular (formula) weight	MW	Sum of atomic weights of all elements in a chemical formula
Millimole	mmol (mM)	Molecular (formula) weight of a substance in mg, equals 1 mM
Milliequivalent	mEq	Weight, in mg, of an element that combines or replaces 1 mg (1 mmol) of hydrogen (H^+)
Milliosmole	mOsm	Always contains 6.0×10^{23} molecules and equals 1 mmol of a nondissociable substance
Milliequivalent per liter	mEq/l	= mmol/l × valence = [(mg/dl × 10)/MW] × valence

depends upon intravenous administration of a known amount of a dye or radioisotope-tagged substance that distributes only in the compartment of interest. This is followed by assessment of dye or radioisotope concentration in the compartment. Ideally, the indicator substance must distribute rapidly and homogeneously, remain in the space to be measured, not be metabolized or bound, and be nontoxic. The volume of distribution (Vd) of a drug, or in this case a volume marker, may be derived according to the same principles of pharmacokinetics described in Chapter 3.

Total body water (TBW) is approximated at 60% of body weight, but this figure varies from 50 to 75% depending upon age, lean body mass, and individual animal variations. Since fat is lower in water content than lean tissue, obesity is associated with decreased TBW (approximately 50%). To avoid overhydration of obese patients, fluid requirements are best estimated based on lean body mass. Very young animals are about 70–75% water, with TBW declining with advancing age. Table 23.2 provides estimates of selected volumes in dogs. TBW is broadly divided into two types: intracellular (ICF) and extracellular fluid (ECF). The ECF is further divided into four subcompartments: plasma volume, interstitial lymph fluid, transcellular fluid, and fluid present in dense connective tissue and bone. Table 23.3 provides experimentally derived blood volumes as percentages of body weight for various species.

Transcellular fluid is found in diverse locations, including cerebrospinal fluid, pleural cavity, gastrointestinal tract, bladder, synovia, aqueous humor, and peritoneal cavity. Transcellular volumes vary greatly from monogastrics (1–6%) to horses and ruminants (10–15%), dependent largely upon the amount of fluid sequestered in the gastrointestinal tract. Transcellular volumes are not readily mobilized during volume deficits but are of importance in terms of drug disposition and equilibrium. In certain disease processes, transcellular fluids may accumulate, causing ascites, hydropericardium, hydrothorax, synovitis, or other conditions, depending on the location of fluid accumulation.

Fluid and Electrolyte Distribution

Body solutes are not distributed homogeneously throughout TBW. Like drugs, every solute has a defined space or volume of distribution that can be assessed experimentally. As with estimation of body compartment volumes, determination of solute distribution is limited by the features of the labeled solute used. Because

Cations	mEq/l	Anions	mEq/l
Sodium	135–160	Chloride	110–125
Potassium	3–5	Bicarbonate	18–22
Calcium (total calcium 5–10 mM/l)	4–6	Phosphate	1–3[a]
Magnesium	1–3	Sulfate	1–2
Trace elements	1	Lactate	1–2
		Other organic acids	3–5
		Protein	10–16
Total	144–175		144–175

[a] Phosphate exists in variable proportions of phosphate and monohydrogen and dihydrogen phosphate, so no valance can be identified and the number of mEq/l is therefore an estimate (Gross, 1994).

normal vascular endothelium is largely impermeable to formed blood elements and plasma protein, these cells and solutes are usually limited to the plasma. Vascular endothelium is freely permeable to ionic solutes, and the concentration of these ions is almost the same in interstitial as in plasma fluid. Table 23.4 provides estimations of ion composition in plasma of normal mammals.

The volume of ICF and ECF compartments is determined by the number of osmotically active particles in each space. ECF osmolality can be estimated from the following formula (Rose, 1989):

$$\begin{aligned}&\text{ECF osmolality (mOsm/kg)} = 2([\text{Na}^+] + [\text{K}^+])\\&+ \text{glucose}/18 + \text{blood urea nitrogen(BUN)}/2.8\end{aligned}$$

Because cell membranes are permeable to urea and K^+, these substances contribute only ineffective osmoles, as described earlier. At normal blood glucose concentrations, Na^+ is the primary determinant of effective ECF osmolality. Because Na^+ is the most abundant and osmotically active ECF cation, maintenance of an extracellular-to-intracellular sodium gradient is critical and is accomplished by the cell membrane Na^+,K^+-adenosine triphosphatase (ATPase) pump. This pump is also responsible for maintaining appropriate concentrations of intracellular K^+. Because K^+ is the most abundant intracellular cation, the ratio of intracellular-to-extracellular K^+ concentration is the major determinant of the resting cell membrane potential (−70 to −90 mV). Because all body fluid spaces are isotonic with one another, the effective osmolality of the ICF, and indeed TBW, must be equal to that of the ECF. Acute addition or loss of fluid and/or solutes from the body inevitably results in alterations in compartment volumes and tonicity. Homeostatic shifts of fluid between compartments must then occur to return the system to isotonicity.

The critical distribution of water between the plasma and the interstitium is maintained by the colloidal osmotic pressure of plasma protein (oncotic pressure). This is the force that draws water into the capillaries and balances the hydrostatic pressure driving water out. These so-called "Starling forces" describe the capillary balance between forces that favor filtration of water from plasma and those that retain vascular volume:

$$\text{Net filtration (NF)} = K_f[(P_{\text{cap}} - P_{\text{if}}) - (\pi_p - \pi_{\text{if}})]$$

where K_f represents permeability of the capillary wall, P represents hydrostatic pressure in the capillaries (P_{cap}) (blood) or tissues (P_{if}) (interstitial fluid), and π represents oncotic pressure generated by plasma protein (π_p) or filtered proteins and glycosaminoglycans in the interstitium (π_{if}). Applying Starling's relationships yields the prediction that hypoproteinemia (decreased π_p) will increase loss of vascular fluid and that water depletion (with a relative increase in π_p and a decrease in P_{cap}) will promote reabsorption of interstitial fluid into the vasculature (Kohn and DiBartola, 1992). The volume of intracellular water in a given tissue is maintained by intracellular protein. As plasma water decreases, plasma protein competes with intracellular protein for water, resulting in cellular dehydration. Clinical alterations in plasma osmolality may be assessed by comparing measured osmolality in a patient to calculated serum osmolality as determined using Na^+, K^+, glucose, and BUN measurements (see the ECF osmolality equation provided above). Observed changes in the osmolal gap (difference between measured osmolality and the osmolality calculated from normal concentrations) may be useful in determining the presence of unmeasured osmoles associated with toxic substances such as ethylene glycol. The osmolal gap may also be useful in assessing shifts in plasma sodium concentration (Kohn and DiBartola, 1992).

The number of cations in the ECF must equal the number of anions in order to maintain electroneutrality. In practice, only selected cations and anions are routinely measured in a clinical setting. Calculation of the difference between the commonly measured cations and anions in ECF yields the unmeasured anions, or anion gap (Oh and Carrol, 1977; Emmett and Narins, 1977). The anion gap calculation can be useful in assessing the etiology of metabolic acidosis and will be discussed in this context subsequently.

Water, Sodium, and Chloride

Homeostasis

Daily intake of water, nutrients, and minerals is normally balanced by daily excretion of these substances. Water turnover is the term used to describe input and output of body water over a given period of time. Values for water turnover, per 24 hours, in various domestic animals resting in cages or stalls range from about 40 to 132 ml/kg/day. The range is influenced by species, age, and physiological state (Adolph, 1939; Smith, 1970 unpublished data). Extremes of temperature, psychological state, disease, and other variables may change water demands markedly. Water turnover in mature dogs is approximated as 40–60 ml/kg/day, while immature and lactating animals may turn over approximately twice this amount (Muir and DiBartola, 1983). Maintenance fluid needs are defined as the volume of fluid required daily to maintain an animal in zero fluid balance, that is, no net gain or loss of water.

Normal water intake occurs in response to thirst, which is stimulated by plasma hypertonicity and/or contracted ECF volume. Plasma hypertonicity, the primary stimulus, prompts osmoreceptors in the supraoptic and paraventricular nuclei of the hypothalamus to release vasopressin, also called antidiuretic hormone (ADH), which is released into the circulation at the level of the pituitary neurohypophysis. Binding of vasopressin to receptors in the distal nephron and renal collecting duct cells activates adenylyl cyclase and increases intracellular cyclic AMP. A protein kinase cascade initiated by activation of protein kinase A results in opening of luminal water pores in the tubule cell. Permeability of the collecting duct to water and reabsorption of water increase. Sustained release of vasopressin depends additionally upon calcium cycling across the plasma membrane and activation of protein kinase C–dependent pathways. Prostaglandins inhibit the renal response to vasopressin. Drugs with anticyclooxygenase activity that inhibit prostaglandin synthesis thereby enhance the action of endogenous vasopressin. Figure 23.1 summarizes the effects of selected drugs and electrolytes on vasopressin release and action.

If ECF volume and renal perfusion decrease, volume receptors in the renal juxtaglomerular apparatus respond, causing the secretion (or release) of renin, which converts angiotensinogen to angiotensin I. This is the rate-limiting step in the renin–angiotensin system. Angiotensin I is activated to the potent vasoconstrictor angiotensin II in the lung and in endothelial cells throughout the body by angiotensin-converting enzyme (ACE). Angiotensin II stimulates the zona glomerulosa of the adrenal cortex to secrete aldosterone, which, in turn, causes increased reabsorption of sodium from the distal nephron with excretion of K^+ and H^+. Due to the increased concentration of sodium, plasma becomes hypertonic, causing vasopressin release and water retention.

Water intake occurs in response not only to thirst but also to hunger. Water content of food may be as low as 10% (dry food) or as high as 90% (succulent green pasture). Canned pet foods generally contain more than 70% water, and semimoist foods are intermediate (20–40% water) (Lewis and Morris, 1987). Intake of dietary water is governed centrally by appetite control mechanisms rather than by fluid and electrolyte homeostasis. In addition to water intake related to eating and drinking, metabolic water is produced endogenously by catabolism of proteins, fats, and carbohydrates (approximately 5 ml/kg/day) and represents about 10–15% of total water intake in dogs and cats (Anderson, 1983).

Normal water loss occurs via urine, fecal water, and saliva (sensible loss), with insensible losses occurring via evaporation from cutaneous and respiratory epithelia. Insensible losses account for TBW elimination of about 15–30 ml/kg/day in healthy, sedentary animals in a thermoneutral environment (Kohn and DiBartola, 1992).

Metabolic rate, and therefore a portion of daily water turnover, are directly proportional to the ratio of body surface area to total volume. For example, the surface area to volume ratio in a puppy is much larger than in an adult dog and the puppy has a higher basal metabolic rate. Both lead to a much greater evaporative loss of water from the skin per unit volume. Hence, daily water turnover per unit body weight may be nearly twice that of the adult animal. Small, immature animals are therefore at greater risk for insensible water loss than large, mature animals.

The most important and predictable loss of water in healthy, sedentary animals, in a thermoneutral environment, occurs via the urine. Urinary losses can vary from 2 to 20 ml/kg/day. Daily urinary water losses may be divided into obligatory water loss and free water loss (Kohn and DiBartola, 1992). Obligatory water loss represents water eliminated in order to excrete the daily renal solute load. The renal solute load is derived from dietary sources of protein and minerals and consists of urea, Na^+, K^+, Ca^{++}, Mg^{++}, NH_4^+, and other cations, and PO_4^{3-}, Cl^-, SO_4^{2-}, and other anions. Hence, daily renal solute load is a function of the quantity and composition of food ingested. Urea accounts for two-thirds of the urinary solute load in dogs (O'Connor and Potts, 1969).

In normal animals increased urine solute load is eliminated by an increase in urine volume (obligatory water

loss) rather than a marked increase in urine osmolality. Hence, urine osmolality is not generally maximized in order to accomplish steady-state elimination of solutes. Obligatory renal water loss is clinically important for removal of renal solutes but also because this type of water loss will continue even in states of relative water deficit. Free water loss represents water excreted unaccompanied by solute. Excretion of free water is controlled by vasopressin and increases during relative water excess or hypotonicity and decreases during water deficit or hypertonicity. Obligatory fecal water loss occurs in order to excrete fecal solutes. Fecal losses ordinarily account for 2–5% of TBW losses and vary with the species. Feces typically contain 50–80% water (Kohn and DiBartola, 1992).

Renal Regulation of Sodium, Chloride, and Water Excretion

Elimination or conservation of body water and solutes via the kidneys depends upon the processes of glomerular filtration and renal tubular reabsorption and secretion. A major mechanism for conservation of water is urine concentration. The canine kidney can concentrate urine to as much as 2400 mOsm, compared to 1200–1400 mOsm achieved in human urine. Elimination of substances via the urine depends upon renal clearance of each substance from the plasma. The volume of plasma that must be filtered each minute to account for the amount of substance appearing in the urine each minute under steady-state conditions defines renal clearance of that substance.

As much as 20% of cardiac output is directed to the kidneys, with blood entering a renal glomerulus through an afferent arteriole and leaving through an efferent arteriole. Resistance changes in afferent and efferent capillaries regulate glomerular filtration rate (GFR). For discussions of normal and abnormal renal physiological function the reader is referred to any standard physiology text. An understanding of the complexities of renal function is crucial to the understanding of water, acid–base, and electrolyte balances.

As glomerular filtrate flows through the tubules, most of the water (greater than 90%) and varying amounts of solute are reabsorbed into the peritubular capillaries. The composition of the tubular reabsorbate closely approximates that of ECF. Reabsorption is largely achieved by transport of electrolytes and other solutes in two steps: (i) absorption of solutes from tubular fluid into tubular cells and (ii) movement of solutes from tubular cells into the ECF. Several types of transport account for tubular reabsorption of solutes, including passive transport (simple diffusion), facilitated diffusion, active transport, and cotransport. These mechanisms are discussed in more detail in the context of diuretic drugs (Chapter 24) and are summarized in Figure 23.2, which depicts some of the functional processes for regulation of salt and water transport in different segments of the nephron.

As much as 60–65% of filtered solute is reabsorbed in the proximal tubule accompanied by osmotically proportional amounts of water. The tubular fluid at the distal portion of the proximal tubule becomes slightly hypoosmotic. Passive reabsorption of substances, especially sodium and chloride, continues in the thin segment of the loop of Henle. The thick ascending limb of the loop of Henle and the distal convoluted tubule are relatively impermeable to water but actively reabsorb solute. Sodium and chloride enter tubular cells in the thick ascending limb of Henle's loop by crossing the luminal membrane coupled to potassium in a proportion of 1 Na^+ : 1 K^+ : 2 Cl^-. Sodium is then actively extruded across the basolateral membrane to maintain intracellular sodium at low levels. Potassium and chloride leave the tubular cell passively. Two consequences of this are decreased concentration of sodium and chloride in the tubular lumen and increased concentration of each in interstitial fluid. A concentration gradient across the tubular epithelium is established, and this becomes multiplied in a longitudinal direction by the countercurrent mechanism. The collecting ducts are responsive to vasopressin, and in its presence the ducts become highly permeable to water. Tubular fluid equilibrates with hyperosmotic interstitium, and hypertonic (concentrated) urine results. In the absence of vasopressin, the

ducts are relatively impermeable to water. In this case, sodium and chloride have been reabsorbed proximally to the collecting ducts, tubular fluid is hypoosmotic, and voided urine is dilute (Thier, 1987).

Renal reabsorption of sodium in the distal nephron is increased by aldosterone, a mineralocorticoid synthesized in the zona glomerulosa of the adrenal cortex. Aldosterone is produced and released in response to stimulation by angiotensin II, hyperkalemia, and by a decrease in dietary sodium intake. Adrenocorticotropic hormone (ACTH) and hyponatremia play permissive roles in promoting aldosterone secretion. Increased dietary sodium and atrial natriuretic peptide (ANP) decrease aldosterone production. ANP is a polypeptide released from atrial and ventricular myocytes in response to atrial distention associated with volume expansion. ANP causes vascular smooth muscle relaxation, inhibits production of aldosterone in the adrenal glands, and blocks the production of angiotensin II. Study results suggest that parathyroid hormone (PTH) is required for augmented ANP secretion in response to acute volume loading in rats. PTH may play an important role in the regulation of fluid homeostasis via control of ANP (Geiger et al., 1992).

In general, chloride is reabsorbed with sodium throughout the nephron. As previously noted, chloride is exchanged in a ratio of 1 Na^+ : 1 K^+ : 2 Cl^- in the thick ascending limb of Henle's loop during sodium reabsorption. Because the cotransporter in this exchange has a very high affinity for both Na^+ and K^+, luminal Cl^- concentration is normally the rate-limiting step in NaCl entry into the cell (Gregor and Velazquez, 1987). Additional active and passive processes contribute to proximal Cl^- reabsorption in the renal tubules. Chloride exchange for formate appears to occur via an anion exchanger in the luminal membrane. Low concentrations of filtered formate combine with H^+ to form formic acid (HF) in the tubular lumen. Because HF is uncharged, it moves freely into the tubular cell. Two additional mechanisms set the stage for conversion of HF back to formate and H^+. First, basolateral Na^+,K^+-ATPase pumps maintain a low intracellular sodium concentration, and this, in turn, allows for the continued exchange of Na^+-H^+ across the luminal membrane. As Na^+ is reabsorbed and H^+ is secreted, the interior of the cell is left with a lower $[H^+]$ than the tubular lumen. Under these conditions HF is converted back to H^+ and formate, providing for continued chloride–formate exchange. Reabsorbed chloride is returned to the ECF across the basolateral membrane by selective Cl^- channels and a K^+-Cl^- cotransporter (Rose, 1994). Additional transport mechanisms in type B intercalated cells in the cortical collecting tubule may exchange bicarbonate for chloride. The favorable inward concentration gradient for chloride (lumen concentration greater than inside the cell) presumably provides the energy for bicarbonate secretion via this mechanism (Bastani et al., 1991).

Understanding the mechanisms for renal regulation of acid–base balance and electrolyte transport is increasingly dependent upon use of transgenic mice in which the function and regulation of key transporter proteins can be assessed (Cantone et al., 2006).

Disorders of Water, Sodium, and Chloride Balance

Types of Dehydration

Dehydration may be considered in three general categories: hypertonic, isotonic, and hypotonic. Pure water loss and loss of hypotonic fluid lead to hypertonic dehydration. As pure water is lost from the ECF, fluid shifts from the intracellular to the extracellular compartment in response to increased osmolality. The resulting proportionate distribution of volume loss results in fewer clinically detectable signs of volume depletion in the patient. Causes of dehydration associated with pure water deficit include hypodypsia due to neurological disease, diabetes insipidus, respiratory losses during exposure to elevated temperatures, fever, and inadequate access to water.

Loss of hypotonic fluid, as compared to pure water, results in a greater depletion of ECF volume since there is less osmotic drive to pull volume from the intracellular space. Hypotonic fluid losses are common and have been subclassified as extrarenal and renal. Extrarenal losses could include gastrointestinal (e.g., vomiting or diarrhea) or third-space loss (e.g., pancreatitis, peritonitis, as a result of surgery or cutaneous injury). Third spacing is a term used to describe extravasation of fluid from the vascular compartment into extravascular spaces. As tonicity of lost fluid approaches or exceeds normal plasma osmolality (about 300 mOsm/kg), disproportionate depletion of ECF causes more evident clinical signs of dehydration. Volume depletion would likely be the most clinically apparent in cases of hypertonic fluid loss.

Estimations of percent dehydration based on clinical signs are given in Table 23.5. Skin elasticity is a useful indicator of hydration status. However, age of the animal, body condition, and the technique used for evaluating elasticity may affect hydration assessment. With advancing age or cachexia, loss of fat and protein may account for decreased skin elasticity unrelated to hydration. Conversely, obese animals are likely to retain skin elasticity longer in the face of dehydration. Possibly as a result of variations in elastin content of skin, some species display smaller changes in elasticity for a given degree of dehydration. This may be clinically important in the horse. While dry mucous membranes can indicate dehydration, open-mouthed breathing associated with respiratory disease may cause misleading mucous membrane dryness. Degree of enopthalmos is considered a very useful parameter in assessment of dehydration in large animals.

Table 23.5 Physical findings in dehydration

Percent dehydration	Clinical signs
4 or less	History of fluid loss, mucous membranes still moist, evidence of thirst
5–6	Subtle loss of skin elasticity, slight delay in return of skin to normal position, hair coat dull, mucous membranes slightly dry but tongue still moist
7–8	Definite delay in return of skin to normal position, both mucous membranes and tongue may be dry, eyeballs may be soft and sunken, slight prolongation of capillary refill time
9–11	Tented skin does not return to normal position, definite prolongation of capillary refill time, eyes definitely sunken in orbits, all mucous membranes dry, may be signs of shock such as tachycardia, cool extremities, rapid and weak pulses
12–15	Definite signs of shock and circulatory collapse, death is imminent

For example, the measured gap between the eyeball and orbit has been included as a guideline for assessment of dehydration in neonatal calves. A gap less than 0.5 cm is correlated with 9–10% dehydration, and a gap greater than 0.5 cm suggests 11–12% loss of hydration (Naylor, 1996). A study in diarrheic calves evaluated several clinical and laboratory parameters to determine which were most useful in assessment of dehydration. Factors assessed included extent of enophthalmos, skin-tent duration on neck, thorax, and upper and lower eyelids, heart rate, mean central venous pressure, peripheral (extremities) and core temperatures, packed-cell volume, and hemoglobin and plasma protein concentration. The best predictors of degree of dehydration were extent of enophthalmos, skin elasticity on neck and thorax, and plasma protein concentration (Constable et al., 1998). Laboratory parameters such as hematocrit, plasma protein, and osmolality are often useful, but assessment should include consideration of possible preexisting derangements, such as anemia or hypoproteinemia, that could confound interpretation. If an accurate previous body weight is known, serial changes in weight are considered a very useful and accurate measurement in determining degree of dehydration.

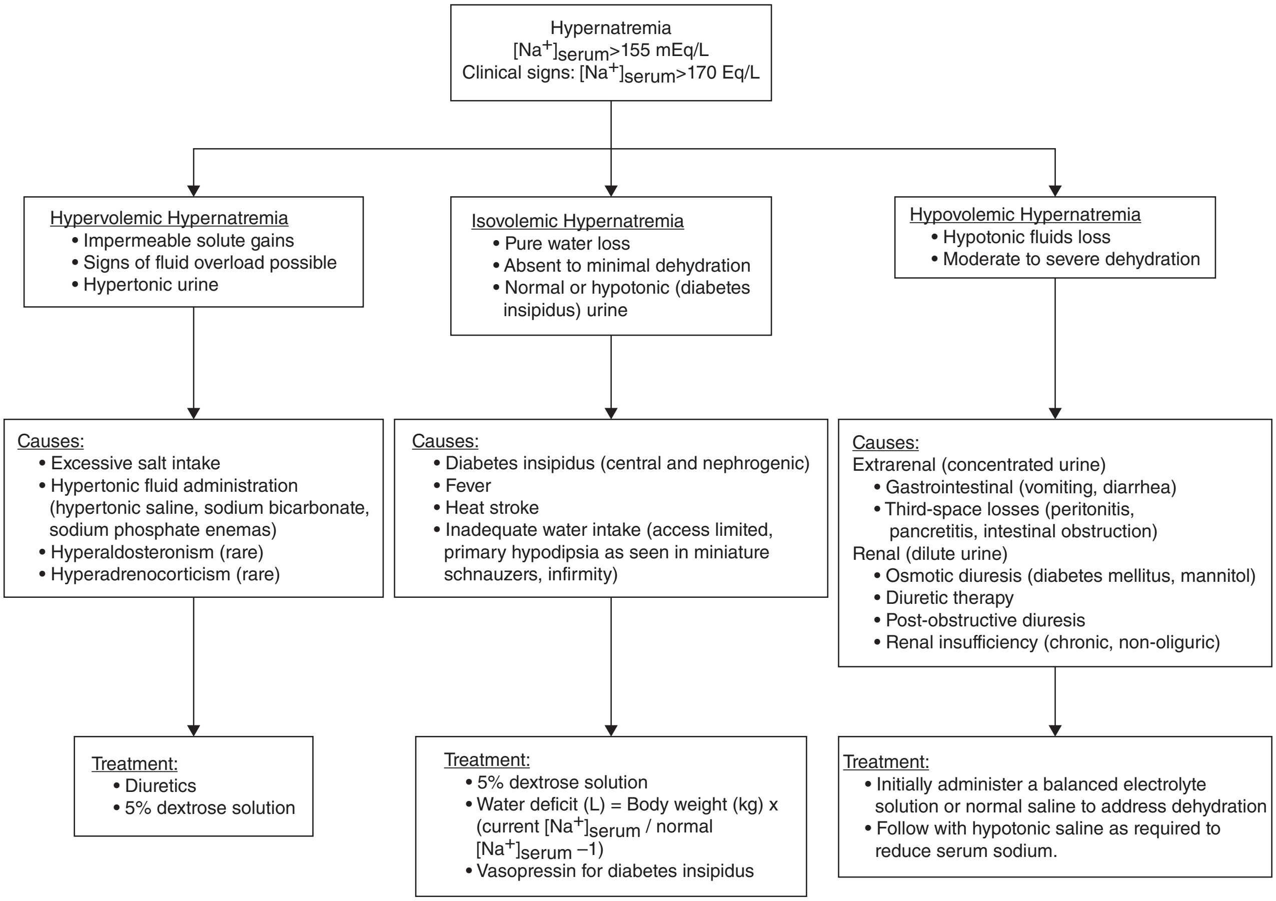
Hypernatremia

As the most important and abundant ECF cation, sodium is essential for proper maintenance of membrane potentials, initiation of action potentials, and, according to strong ion difference theory, maintenance of acid–base balance. Plasma sodium concentration and plasma osmolality generally vary in parallel since sodium and its associated anions account for greater than 95% of plasma osmolality. Plasma sodium concentration reflects the ratio of body sodium ion concentration to TBW. Total body sodium content, however, is independent of plasma sodium concentration and may be increased, decreased, or unchanged in the presence of hyper- or hyponatremia.

Clinical signs associated with alterations in serum sodium are more related to the rapidity of change rather than to the magnitude of sodium increase or decrease. Hypernatremia (e.g., >155 mEq sodium/l in dogs) and ECF hypertonicity can be caused by a loss of pure water, a loss of hypotonic fluid (extrarenal or renal), or a gain of impermeable sodium-containing solute (Figure 23.3). Clinical signs of hypernatremia are usually observed in dogs and cats as sodium concentration approaches and exceeds 170 mEq/ml. The signs seen are related to the osmotic movement of water out of cells. Negative effects of cellular dehydration are most pronounced in the brain and lead to the characteristic neurological deficits associated with hypernatremia. These deficits include abnormal behavior and mentation, ataxia, seizures, and coma. The more rapidly water shifts out of brain cells, the greater the chance that decreased brain volume will lead to rupture of cerebral vessels and focal hemorrhage (Arieff and Guisado, 1976). If sodium concentration or concentration of sodium-containing impermeable solute increases slowly, the brain attempts to adapt to the hypertonic state by production of intracellular solutes (e.g., sugars, amino acids) known as “idiogenic” osmoles. Production of these osmotically active substances protects the cell by retaining intracellular volume and preventing cellular dehydration. In addition to neurological deficits, other clinical signs of hypernatremia include thirst, anorexia, lethargy, vomiting, and muscle weakness. If hypernatremia is related to hypotonic fluid loss, then clinical signs of dehydration (as previously described) may be present. If a gain of sodium has caused the hypernatremia, volume overload may be a problem, especially in patients with cardiac disease.

Restoration of ECF volume and tonicity is of primary importance in treatment of hypernatremia. Volume replacement must be accomplished slowly to avoid rapid shifts in plasma osmolality. In general, the rate of fluid administration is determined by the rate of onset of the hypernatremia. When treating chronic hypernatremia, the serum sodium concentration should drop at a rate that does not exceed 0.7 mEq/l/h (O’Brien, 1995). If plasma osmolality drops quickly, water may be attracted intracellularly by idiogenic osmoles, resulting in development of cerebral edema.

Patients with clinical hypernatremia are also often dehydrated, and need volume resuscitation. Custom fluid combinations can be designed to gradually bring down sodium while being able to give high rates of fluids to replace volume. In the case of pure-water loss, volume can be replaced with 5% dextrose in water over a 48- to



Hypernatremia
[Na+]serum>155 mEq/L
Clinical signs: [Na+]serum>170 Eq/L
Hypervolemic Hypernatremia
• Impermeable solute gains
• Signs of fluid overload possible
• Hypertonic urine
Isovolemic Hypernatremia
• Pure water loss
• Absent to minimal dehydration
• Normal or hypotonic (diabetes insipidus) urine
Hypovolemic Hypernatremia
• Hypotonic fluids loss
• Moderate to severe dehydration
Causes:
• Excessive salt intake
• Hypertonic fluid administration (hypertonic saline, sodium bicarbonate, sodium phosphate enemas)
• Hyperaldosteronism (rare)
• Hyperadrenocorticism (rare)
Causes:
• Diabetes insipidus (central and nephrogenic)
• Fever
• Heat stroke
• Inadequate water intake (access limited, primary hypodipsia as seen in miniature schnauzers, infirmity)
Causes:
Extrarenal (concentrated urine)
• Gastrointestinal (vomiting, diarrhea)
• Third-space losses (peritonitis, pancretitis, intestinal obstruction)
Renal (dilute urine)
• Osmotic diuresis (diabetes mellitus, mannitol)
• Diuretic therapy
• Post-obstructive diuresis
• Renal insufficiency (chronic, non-oliguric)
Treatment:
• Diuretics
• 5% dextrose solution
Treatment:
• 5% dextrose solution
• Water deficit (L) = Body weight (kg) x (current [Na+]serum / normal [Na+]serum −1)
• Vasopressin for diabetes insipidus
Treatment:
• Initially administer a balanced electrolyte solution or normal saline to address dehydration
• Follow with hypotonic saline as required to reduce serum sodium.

Figure 23.3 Summary of classification, causes, and treatment of hypernatremia. See text for additional details of treatment.

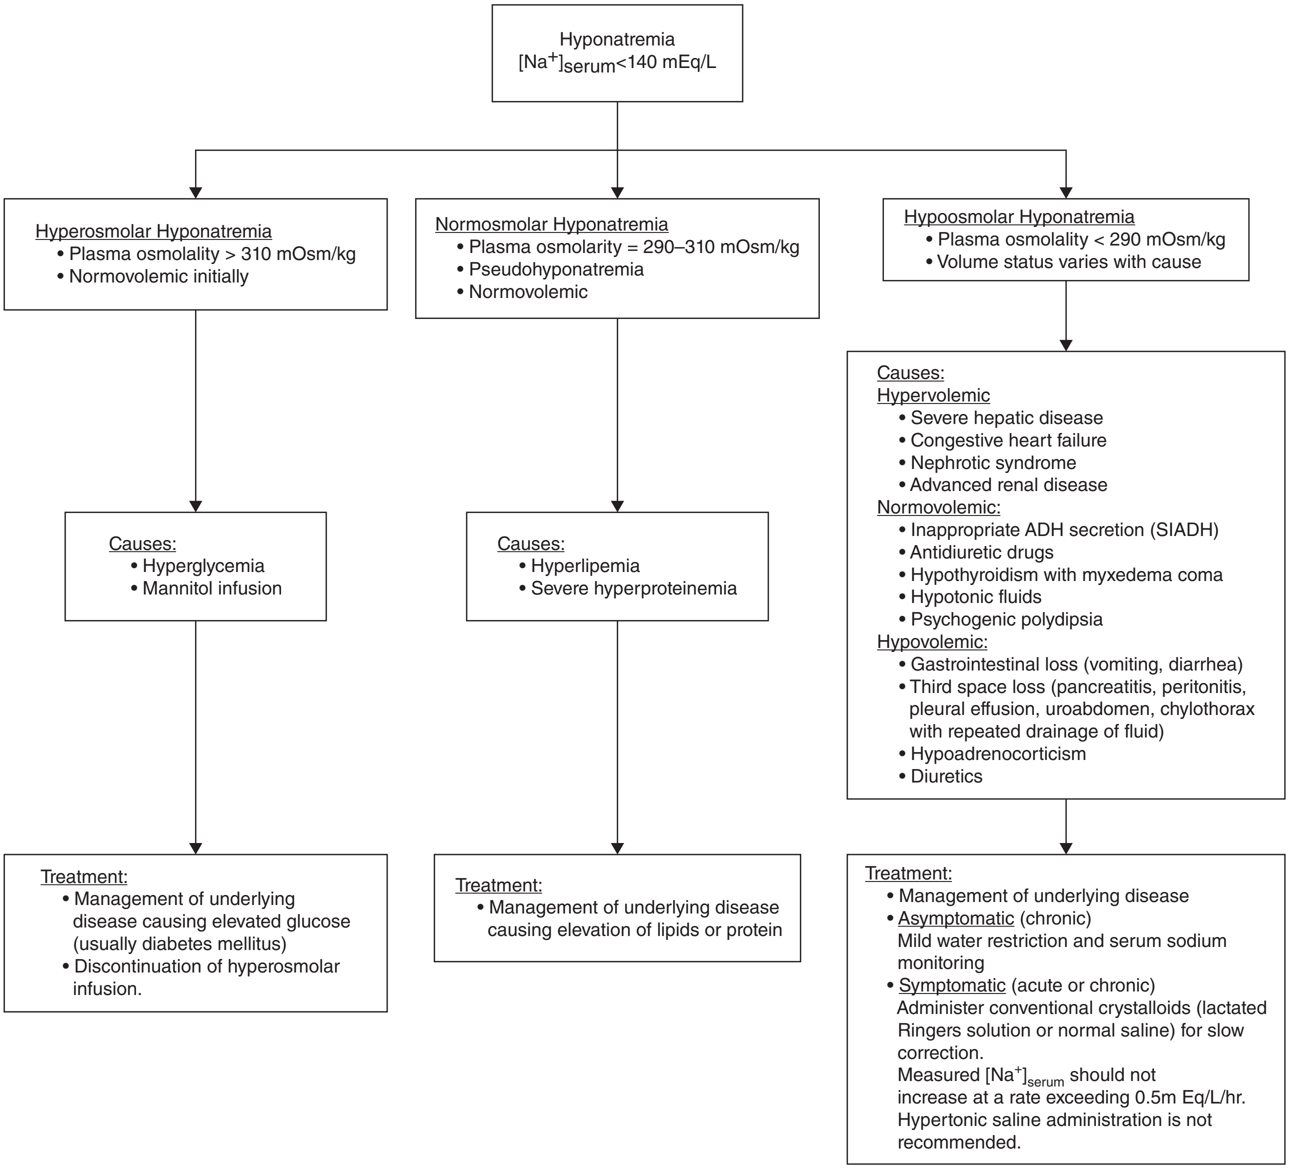
72-hour period. Since the dextrose ultimately enters cells and is metabolized, 5% dextrose administration is essentially replacement with pure water. Use of a 1 : 1 mixture of normal saline with 5% dextrose solution yields an isotonic solution of 2.5% dextrose, 0.45% saline that has also been utilized. This solution decreases plasma tonicity more slowly and decreases the chance for cerebral edema. Hypotonic fluid losses should generally be replaced with an isotonic crystalloid solution. If hypernatremia has resulted from addition of sodium or sodium-containing impermeable solute, then administration of 5% dextrose and water should be accomplished cautiously to avoid pulmonary edema. Diuretics may be useful in promoting saluresis (sodium excretion) as ECF volume is restored (Marks, 1998).

Evaluation and treatment of hypernatremia in critically ill cats was reviewed with emphasis on the importance of careful monitoring and early recognition of signs for positive therapeutic outcomes (Temol et al., 2004).

Hyponatremia

Causes of hyponatremia (<135–140 mEq sodium/l) are best categorized if two additional variables, osmolality and hydration, are also considered. As indicated in Figure 23.4, the more common causes of hyponatremia are accompanied by decreased plasma osmolality (<290 mOsm/kg) with or without volume depletion. If volume depletion exists with hyponatremia, then loss of body sodium has exceeded water loss. Physiological responses to hypovolemia lead to impaired water excretion and a relative dilution of the sodium remaining in body fluids. Hypovolemia causes decreased renal perfusion and GFR, leading to a decline in water excretion. Slower movement of filtrate through renal tubules enhances isosmotic reabsorption of salt and water in the proximal tubules and decreases presentation of tubular fluid at distal diluting sites. Additionally, hypovolemia prompts vasopressin release, further impairing water elimination. Finally, thirst related to hypovolemia results in consumption of low-sodium fluids that also dilute existing plasma sodium (DiBartola, 1992c).

Hyponatremia accompanied by hypervolemia and low plasma osmolality occurs in clinical disorders where there is a physiological perception of volume depletion by in vivo volume detectors. The physiological response



Hyponatremia
$[Na^+]_{serum}$<140 mEq/L

Hyperosmolar Hyponatremia
- Plasma osmolality > 310 mOsm/kg
- Normovolemic initially

Causes:
- Hyperglycemia
- Mannitol infusion

Treatment:
- Management of underlying disease causing elevated glucose (usually diabetes mellitus)
- Discontinuation of hyperosmolar infusion.

Normosmolar Hyponatremia
- Plasma osmolarity = 290–310 mOsm/kg
- Pseudohyponatremia
- Normovolemic

Causes:
- Hyperlipemia
- Severe hyperproteinemia

Treatment:
- Management of underlying disease causing elevation of lipids or protein

Hypoosmolar Hyponatremia
- Plasma osmolality < 290 mOsm/kg
- Volume status varies with cause

Causes:
Hypervolemic
- Severe hepatic disease
- Congestive heart failure
- Nephrotic syndrome
- Advanced renal disease

Normovolemic:
- Inappropriate ADH secretion (SIADH)
- Antidiuretic drugs
- Hypothyroidism with myxedema coma
- Hypotonic fluids
- Psychogenic polydipsia

Hypovolemic:
- Gastrointestinal loss (vomiting, diarrhea)
- Third space loss (pancreatitis, peritonitis, pleural effusion, uroabdomen, chylothorax with repeated drainage of fluid)
- Hypoadrenocorticism
- Diuretics

Treatment:
- Management of underlying disease
- Asymptomatic (chronic)
  Mild water restriction and serum sodium monitoring
- Symptomatic (acute or chronic)
  Administer conventional crystalloids (lactated Ringers solution or normal saline) for slow correction.
  Measured $[Na^+]_{serum}$ should not increase at a rate exceeding 0.5m Eq/L/hr.
  Hypertonic saline administration is not recommended.

Figure 23.4 Summary of classification, causes, and treatment of hyponatremia. See text for additional details of treatment.

is volume expansion. For example, in congestive heart failure, decreased cardiac output is sensed as volume depletion by baroreceptors. Release of vasopressin impairs water excretion, leading to expanded vascular volume. Decreased effective circulating volume and decreased renal perfusion also lead to activation of the renin–angiotensin–aldosterone system. Enhanced renal retention of sodium contributes to expanded vascular volume. In cirrhosis and the nephrotic syndrome, hypoalbuminemia and decreased oncotic pressure may contribute to decreased effective circulating volume and, ultimately, vasopressin release and volume expansion. Other features of hepatic and renal disease also contribute to decreased circulating volume and/or impaired water excretion (DiBartola, 1992c).

Hyponatremia is relatively less common when associated with increased plasma osmolality. The most frequent cause of sodium decreases in the presence of increased plasma osmolality is the increased circulating glucose levels associated with diabetes mellitus. Each 100 mg/dl increase in glucose results in a measured decrease of serum sodium by 1.6 mEq/l (Katz, 1973). In response to the increased concentration of serum glucose, water shifts from the intracellular to the extracellular compartment, resulting in dilution of measured sodium. Serum osmolality remains high due to elevated glucose concentrations. Hyponatremia associated with normal plasma osmolality is referred to as pseudohyponatremia. The decreased sodium concentrations are spurious and are almost universally related to technical difficulties in sodium measurement when plasma lipid or protein concentrations are high.

As with hypernatremia, clinical signs of hyponatremia are more severe if sodium concentration changes rapidly than if it changes over a more prolonged period of time. If sodium concentrations and plasma osmolality decrease quickly, water shifts out of the ECF and into cells. The central nervous system (CNS) is most affected by a rapid fluid shift, which, in hyponatremia, results in development of cerebral edema. If onset of hyponatremia is slow, the brain can adjust cell volume by decreasing intracellular osmolality and preventing influx of water from the ECF. Patients with chronic hyponatremia will also adjust intracellular osmolality to an extent that clinical signs may not be obvious even though sodium concentrations are quite low.

Treatment of hyponatremia varies with etiology of the disorder. The goals of therapy are to manage the underlying disease and, if necessary, to increase serum sodium and osmolality. Infusion with conventional crystalloid solutions (e.g., normal saline or lactated Ringer's solution) is reported to accomplish sodium and volume replacement in hyponatremic, hypovolemic patients (DiBartola, 1992c). Use of hypertonic saline solutions is not recommended since overly rapid correction of hyponatremia may do more harm than good. Chronic hyponatremia, in which the brain has adjusted to the decrease in osmolality and sodium, must be handled cautiously to avoid brain dehydration and injury, including osmotic demyelination syndrome. This syndrome, often occurring several days after correction of hyponatremia, results from areas of demyelination caused by treatment-induced increases in serum sodium concentration. Dogs with asymptomatic chronic hyponatremia are best treated by mild water restriction and monitoring of serum sodium. Chronic, symptomatic dogs should be treated such that the rate of increase of serum sodium does not exceed 10–12 mEq/l/day (0.5 mEq/l/h) (DiBartola, 1998). Again, the most important therapeutic goal in management of hyponatremia should be treatment of the underlying disease.

Hyperchloremia

Fluid loss associated with small bowel diarrhea often results in greater loss of HCO_3^- than chloride due to loss of alkaline pancreatic secretions and bile and HCO_3^- secretion in exchange for Cl^- in the ileum. The resulting hyperchloremic metabolic acidosis is characterized by a normal anion gap. Additional causes and treatment for hyperchloremic metabolic acidosis will be considered subsequently under the heading of metabolic acidosis. Please refer to the discussion of hypernatremia for treatment of hyperchloremia associated with loss of free water.

Hypochloremia

Hypochloremia may be seen in patients with fluid losses due to vomiting or excessive diuretic administration. Hypochloremic metabolic alkalosis may develop in these cases because an excess of chloride is lost, leading to decreased filtered Cl^- in the renal tubules. As previously noted, activity of the Na^+-K^+-$2Cl^-$ cotransporter in the luminal membrane of the macula densa cell is primarily determined by the availability of Cl^-. In hypochloremia, less Cl^- is delivered, resulting in less NaCl reabsorption, promotion of renin release leading to secondary hyperaldosteronism, and increased distal H^+ secretion. If further Na^+ reabsorption does occur, then Na^+ must be accompanied by an anion other than chloride, usually bicarbonate, or must be exchanged for a secreted cation, either H^+ or K^+. In addition, bicarbonate secretion in exchange for chloride, which is thought to occur in intercalated cells of the cortical collecting tubule, will decrease since this process is presumably driven by a favorable inward gradient for Cl^-. As luminal $[Cl^-]$ decreases, the gradient is dissipated and bicarbonate is retained in the system. All of the foregoing mechanisms promote retention of base and excretion of H^+, leading to a hypochloremic metabolic alkalosis (Rose, 1994). Treatment with chloride-replete fluid such as normal saline is usually adequate to resolve chloride-responsive alkalosis. Potassium depletion may also promote a metabolic alkalosis and should be addressed as needed by addition of potassium chloride to fluids.

Potassium

Homeostasis

As the major intracellular cation, potassium concentrations inside (145 mEq/l) and outside (3.5–5.5 mEq/l) the cell are maintained by the Na^+,K^+-ATPase pump. Under normal circumstances each pump actively transports three sodium ions out of and two potassium ions into the cell, but the ratio can change depending upon the circumstances. The ratio of intra- to extracellular concentration of potassium ($[K^+]_i/[K^+]_o$) is the major determinant of resting membrane potential. Resting membrane potential is crucial to normal membrane excitability associated with cardiac conduction, muscle contraction, and nerve impulse transmission.

The normal dietary intake of potassium is much more than the body requires. About 90% of this intake is excreted in the urine, with the remainder of what is not required eliminated in the stool. Plasma potassium concentration is determined by the movement of potassium into or out of cells. Two important factors stimulating the transport of potassium into cells are insulin and β-adrenergic stimulation (Clausen and Flatman, 1987).

Aldosterone is the primary determinant of potassium secretion across renal tubular epithelial surfaces.

Renal Regulation of Potassium Excretion

Most filtered potassium (60–80%) is reabsorbed in the proximal tubule. In the early proximal tubule, potassium enters the tubular cell at the luminal surface by active transport. The intracellular concentration of potassium is high, and the lumen of the tubule is negatively charged relative to the interior of the early proximal tubular cell. Potassium passively exits the basolateral membrane of the tubular cell down a favorable chemical concentration gradient. In the mid-to-late proximal tubule, the tubular lumen is relatively more positively charged than the tubular cell interior. This favors the passive reabsorption of potassium. Potassium again exits on the basolateral side of the tubular cell down a concentration gradient. Potassium reabsorption by intercalated cells in the distal nephron is similar to the process in the early proximal tubule and involves active transport at the luminal cell membrane followed by passive diffusion from the cell at the basolateral membrane. Tubular secretion of potassium is aldosterone mediated and occurs in the distal nephron (late distal tubule or connecting tubule of the collecting duct system) primarily in the "principal" cells of the collecting tubules. Additional information on mechanisms of collecting duct system reabsorption and secretion is given in Chapter 24 (Figure 24.2). Principal cells are rich in Na^+,K^+-ATPase and respond to aldosterone by increasing the number and activity of Na^+,K^+-ATPase pumps in the basolateral membrane. The increasing luminal membrane permeability to sodium causes greater lumen negativity relative to the tubular cell interior and increases luminal permeability to potassium. This facilitates potassium secretion into the tubule lumen. Aldosterone-stimulated Na^+,K^+-ATPase actively pumps potassium out of the peritubular fluid through the basolateral tubular cell membrane. Movement of potassium from the tubular cell through the luminal membrane and into the tubule lumen is favored by relative negativity of the lumen compared to the interior of the distal tubule cell (Black, 1993).

When plasma potassium concentration is low, secretion of potassium by the principal cells is reduced while hydrogen ion secretion may be increased. Active potassium reabsorption by intercalated cells in the distal nephron is also stimulated by a potassium deficit. An additional factor affecting the movement of potassium across tubular cells is related to tubular flow rate. A rapid flow of filtrate through the tubules maximizes the potassium concentration gradient between the tubular cell interior and the lumen of the tubule and enhances potassium excretion. A reduction of tubular flow slows secretion by allowing a relatively greater concentration of potassium to be maintained in the lumen of the distal tubule (DiBartola and Autran de Morais, 1992).

Disorders of Potassium Balance

Disorders of potassium balance have marked effects on excitable membranes. The difference between the resting membrane potential and the membrane potential required for depolarization (threshold potential) determines the excitability of a cell. Hypokalemia makes the resting membrane potential more negative, thereby hyperpolarizing the cell and increasing the difference between resting and threshold potentials. Hyperkalemia causes the resting membrane potential to become more positive, hypopolarizing the cell and causing hyperexcitability. In hyperkalemia, if the resting potential decreases to less than the threshold potential, the cell depolarizes but is incapable of repolarizing, resulting in loss of cell excitability (DiBartola and Autran de Morais, 1992). In cardiac muscle this results in diastolic arrest; in vascular smooth muscle hyperkalemia causes vasoconstriction.

Changes in pH affect the distribution of potassium between the ICF and the ECF. When acidosis is present, potassium moves out of cells in exchange for hydrogen, which moves intracellularly. In the distal tubule more hydrogen, and relatively less potassium, may be exchanged for sodium at the luminal membrane, leading to decreased potassium excretion. Based on these general principles, a clinical rule of thumb predicts that each 0.1 unit decrease in pH will be accompanied by a 0.6 mEq/l increase in serum potassium concentration.

Conversely, in alkalosis potassium tends to move into cells in exchange for extracellular movement of hydrogen. Hypokalemia has been thought to promote alkalosis because less potassium is available to be exchanged for sodium in the distal tubule. Instead, sodium exchanges for hydrogen at the luminal membrane, leading ultimately to reclamation of bicarbonate and increased systemic pH. At the same time that systemic pH is increasing, secreted hydrogen ions exchanged for sodium cause the urine pH to decline.

Although the principles outlined above are commonly stated and widely applied clinically, it is not clear that these explanations are adequate. In acidosis, the effect of pH changes on potassium translocation varies with the nature of the acid anion, blood pH and HCO_3^- concentration, osmolality, hormonal activity, and liver and renal function (DiBartola and Autran de Morais, 1992). Although changes in serum potassium have been documented during acute mineral acidosis caused by HCl or NH_4Cl (Adrogue and Madias, 1981), acute metabolic acidosis caused by organic acids did not increase serum potassium as predicted (Oster et al., 1980; Adrogue and Madias, 1981). In certain conditions (e.g., diabetic ketoacidosis), hyperkalemia may be more directly associated with hyperosmolality and insulin deficiency than with the acidosis itself. In lactic acidosis, increased serum potassium concentration may be the result of release of intracellular potassium caused by cell breakdown associated with decreased peripheral perfusion (Black, 1993). Metabolic acidosis associated with both mineral and organic acids may directly or indirectly stimulate aldosterone secretion. The effects of aldosterone facilitate excretion of the acid load and, presumably, potassium, although one study failed to show any changes in serum potassium concentration (Perez et al., 1980).

Early studies of the effects of hypokalemia on acid–base balance may have overlooked the key role of chloride depletion in causing metabolic alkalosis (DiBartola and Autran de Morais, 1992). When pure potassium depletion is created iatrogenically in rats, metabolic alkalosis results. However, in dogs, potassium deficit with normal chloride levels leads to metabolic acidosis due, presumably, to a distal renal tubular acidification defect (Garella et al., 1979).

Hyperkalemia

Total body potassium may be normal, decreased, or increased with hyperkalemia. Clinical signs of hyperkalemia (>7.5 mEq/l) are generally associated with changes in membrane excitability and are more severe if the increase in potassium has been rapid. Muscle weakness, twitching, and irritability may occur. Electrocardiographically determined cardiac effects may include extrasystoles, intraventricular conduction blocks, high-peaked T waves, altered QT interval, widened QRS interval, decreased amplitude or disappearance of P waves, depressed ST segment, ventricular asystole, or fibrillation.

Causes of hyperkalemia are summarized in Table 23.6. The more common causes are related to decreased urinary potassium excretion. Pseudohyperkalemia related to hemolysis can occur in species that have high red cell potassium concentrations similar to humans. Dogs, sheep, and cattle can be divided into two groups based on Na$^+$,K$^+$-ATPase activity in red cell membranes. Those animals with high activity and high intracellular potassium concentrations are at risk for hyperkalemia caused by hemolysis. Animals with genetically determined low activity and low intracellular concentrations of potassium are unlikely to suffer from pseudohyperkalemia since the concentration of potassium in red cells resembles the concentration in the ECF (DiBartola and Autran de Morais, 1992).

The effects of several different drugs may impact serum potassium concentration. Since potassium uptake by cells is mediated in part by catecholamines at β receptors, beta blockers decrease intracellular potassium movement and increase ECF potassium concentrations. Angiotensin-converting enzyme (ACE) inhibitors may cause hyperkalemia by interfering with angiotensin II–mediated aldosterone secretion. Prostaglandin inhibitors, heparin, and selected potassium-sparing diuretics (e.g., spironolactone) increase serum potassium by decreasing the secretion of aldosterone or by blocking its activity. In many cases drugs alone may not have a marked effect on serum potassium concentration but if combined with a potassium load or decreased renal function may cause clinically significant hyperkalemia.

Table 23.6 Causes of hyperkalemia. Source: Adapted from DiBartola, 1992a. Reproduced with permission of Elsevier.

Decreased excretion
- Urethral obstruction
- Ruptured bladder
- Anuric or oliguric renal failure
- Hypoadrenocorticism
- Gastrointestinal diseases (e.g., trichuriasis, salmonellosis, perforated duodenal ulcers)
- Chylothorax with repeated drainage of the pleural effusion
- Drugs
  - ACE inhibitors (e.g., captopril, enalapril)
  - Potassium-containing drugs (e.g., potassium chloride)
  - Potassium-sparing diuretics (e.g., spironolactone, amiloride, triamterene)
  - Nonsteroidal antiinflammatory agents
  - Heparin

Translocation from the intracellular to extracellular fluid
- Acute mineral acidosis (e.g., HCl or NH_4Cl administration)
- Insulin deficiency (e.g., diabetic ketoacidosis)
- Ischemia reperfusion
- Drugs (e.g., propranolol)
- Acute tumor lysis syndrome
- Hyperkalemic periodic paralysis (rare)

Increased intake (rare)

Pseudohyperkalemia
- Thrombocytosis
- Hemolysis

Treatment of hyperkalemia varies with the severity of the condition in terms of magnitude and rapidity of onset. Emergency treatment is indicated if potassium rises quickly and exceeds 6.0–8.0 mEq/l (Phillips and Polzin, 1998). Serum potassium concentrations less than these do not typically induce life-threatening cardiotoxicity and can usually be managed with administration of potassium-free fluids. More aggressive treatment is necessary if electrocardiographic signs suggest toxicity. Additional measures that may be taken in treatment of severe hyperkalemia are summarized in Table 23.7. Some are directed toward increasing movement of potassium from the extracellular to the intracellular compartment (i.e., glucose, insulin, and sodium bicarbonate), while others are intended to decrease potassium from the ECF by enhanced renal excretion (e.g., diuretics) or decreased gastrointestinal absorption (i.e., orally

Table 23.7 Therapeutic considerations in the management of severe hyperkalemia

- Establish venous access and administer potassium-deficient fluids
- Discontinue potassium intake, including drugs that may promote hyperkalemia
- Administer the following as needed:
  - $NaHCO_3$ (0.5–1 mEq/kg, slowly IV) if animal is acidotic
  - Calcium gluconate (10% solution; 0.5–1 ml/kg slowly IV up to 10 ml maximum)
  - Glucose (20% solution; 0.5–1.0 g/kg IV)
  - Insulin (0.5 IU/kg) and glucose (20% solution; l g/kg; half given IV bolus and the remainder infused over 2 hours)
- Potassium-wasting diuretics (furosemide, chlorothiazide, hydrochlorothiazide)
- Sodium polystyrene (20 g with 100 ml 20% sorbitol) per os or 50 g in 100–200 ml tap water (retention enema)
- Peritoneal dialysis (last resort)

administered potassium-binding resins such as sodium polystyrene sulfonate).

Therapy with calcium gluconate is included as part of the emergency treatment of hyperkalemia because changes in membrane excitability associated with alterations in potassium may be exacerbated by abnormalities in ionized calcium. Ionized calcium affects the threshold potential of a membrane and, when calcium is decreased, brings threshold closer to resting membrane potential, resulting in greater membrane excitability. An increase in ionized calcium has an opposing effect on membrane excitability by increasing the threshold potential and making depolarization more difficult. Hence, hypocalcemia exacerbates hyperkalemia while hypercalcemia counteracts hyperkalemia.

Hypokalemia

Since 97% of total body potassium is intracellular, depletion can occur with no change in plasma potassium concentration or even with an increase if acidosis is present. Clinical signs of hypokalemia (<2.5–3.0 mEq/l) can include weakness of skeletal and respiratory muscles and loss of intestinal smooth muscle tone. As in hyperkalemia, cardiac changes occur as potassium concentration changes. Supraventricular and ventricular arrhythmias are most commonly observed in animals. ECG hallmarks of hypokalemia in humans are flattened or inverted T waves, depressed S-T segment, and the appearance of U waves. Prolongation of the QT interval and U waves have been reported in dogs but are not as consistently seen as they are in humans. Hypokalemia is increasingly recognized as an important clinical problem in cats, especially in association with chronic renal failure and geriatric animals (Phillips and Polzin, 1998). Feline hypokalemic polymyopathy syndrome, characterized by generalized muscle weakness associated with hypokalemia, is often manifest in cats as ventroflexion of the head and a stiff, stilted gait.

Table 23.8 Causes of hypokalemia. Source: Adapted from DiBartola, 1992a. Reproduced with permission of Elsevier.

- *Increased loss*
  - Gastrointestinal (FEK <4–6%)
    - Persistent vomiting of stomach contents
    - Diarrhea
  - Urinary (FEK >4–6%)
    - Chronic renal failure in cats
    - Diet-induced hypokalemic nephropathy in cats
    - Renal tubular acidosis
    - Postobstructive diuresis
  - Excess circulating mineralocorticoid
    - Hyperadrenocorticism
    - Primary hyperaldosteronism (hyperplastic or neoplastic)
    - Diuretics (loop acting, thiazides and osmotic)
    - Antibiotics (penicillins, amphotericin B, aminoglycosides)
- *Translocation from extracellular fluid to intracellular*
  - Alkalemia
  - Overadministration of insulin and glucose-containing fluids
  - Hyperthyroidism
  - Hypokalemic periodic paralysis
  - Possible complication of hypothermia
- *Decreased intake*
  - Unlikely as sole cause

Increased loss associated with the gastrointestinal or the urinary system is a common cause of hypokalemia, as indicated in Table 23.8. Differentiating gastrointestinal from urinary causes of hypokalemia is largely accomplished by clinical signs and physical exam, but fractional potassium excretion rates (FE_K) may also be useful. Fractional potassium excretion can be calculated using the following formula:

$$FE_K = \left(U_K/S_K\right) / \left(U_{CR}/S_{CR}\right) \times 100$$

where U indicates the urine concentration of potassium (K^+) or creatinine (CR), and S indicates the serum concentration.

Treatment of hypokalemia is indicated if significant potassium loss is expected based on history and clinical signs (e.g., vomiting, diarrhea, overzealous use of diuretics) or if clinical signs of hypokalemia are present. Appropriate potassium administration is often required with prolonged fluid therapy. If feasible, oral potassium supplementation is most desirable since this is the safest route of administration. If intravenous potassium supplementation is warranted, the amount administered should be based on clinical status of the animal and measured serum potassium values. Table 23.9 provides approximate potassium dosages for treatment of hypokalemia in small animals. Alternatively, a rule of thumb may be applied in which 20 mEq/l of potassium is supplemented with careful monitoring of changes in serum potassium. An important caution regarding the administration of intravenous potassium is not to exceed a rate

Table 23.9 Potassium supplementation in treatment of hypokalemia

Serum potassium concentration (mEq/l)	Supplement fluids (mEq/l)[a]
3.5 to 4.5	20
3.0 to 3.5	30
2.5 to 3.0	40
2.0 to 2.5	60
<2.0	80

[a] Quantity of potassium to add per liter of fluid. Do not exceed administration rate of 0.5 mEq K^+/kg/h.

of 0.5 mEq/kg/h. Parenteral potassium administration should always be monitored to ensure that rate of potassium addition does not exceed rate of potassium movement into cells.

Principles of Acid–Base Metabolism

Homeostasis

Blood pH is highly regulated and is normally maintained between 7.38 and 7.42. Pulmonary and renal functions are necessary for precise regulation of pH of all body fluids, blood, and extravascular tissues. An acid is defined by Bronsted and Lowry as a substance that can supply H^+ (protons), and a base is defined as a substance that can accept H^+. In aqueous solutions, H^+ are hydrated; therefore, H_3O^+ is considered an acid and is implied by the symbol H^+. Blood pH is the negative logarithm of the hydrogen ion concentration. Although hydrogen ion concentration cannot be measured directly, hydrogen ion activity is measured chemically using a pH electrode. In body fluids, the difference between activity of hydrogen ions and concentration of hydrogen ions is negligible; hence hydrogen ion concentration and pH are commonly referred to in acid–base discussions. The hydrogen ion concentration of blood at pH 7.4 is 40 nmol/l (nanoequivalents per liter) and is therefore approximately a millionfold lower than the blood concentration of electrolytes such as sodium and potassium. Appropriate hydrogen ion concentration is critical in order to maintain body proteins in configurations required for enzymatic and structural function. An increase in hydrogen ion concentration with a decrease in blood pH is termed acidemia and can be caused by pathophysiological processes that cause accumulation of acids in the body. As the concentration of hydrogen ions decreases, and blood pH increases, alkalemia occurs and can be associated with pathophysiological processes that cause accumulation of alkali in the body. The disordered processes leading to acidemia and alkalemia are termed acidosis and alkalosis, respectively.

On a daily basis, an excess of acid (70–100 mEq) is generated in the body as a result of dietary intake and intermediary metabolism. Catabolism of carbohydrate, fat, and protein account for most of this as a result of: oxidation of sulfur-containing amino acids to sulfuric acid; oxidation of phosphoproteins to phosphoric acid; incomplete oxidation of fats and carbohydrates to organic acid; production of lactate/lactic acid during anaerobic glycolysis; and conversion of carbon dioxide and water produced in the tricarboxylic acid cycle to carbonic acid. Buffers throughout the body minimize changes in blood pH associated with alterations of acid–base balance. The most effective physiological buffers have pK_a values between 6.1 and 8.4, with buffering capacity being maximal within one pH unit of the pK_a. Important extracellular buffers include bicarbonate, inorganic phosphates, and plasma proteins.

Most extracellular buffering occurs as a result of the bicarbonate–carbonic acid buffer pair (pKa = 6.1). Equilibrium of this buffer pair is indicated with the following:

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^-$$

The hydration of CO_2 is a rapid reaction in the presence of the enzyme carbonic anhydrase, which is found primarily in red blood cells and renal tubular cells. The dissociation of any acid, in this case carbonic acid, can be described utilizing the concept that the velocity of a reaction is proportional to the product of the concentration of the reactants. In the case of the bicarbonate buffer system, the carbonic anhydrase–catalyzed hydration of CO_2 to form H_2CO_3 reaches equilibrium almost instantaneously, with the number of dissolved CO_2 molecules far exceeding the number of carbonic acid molecules. By defining dissociation constants and rearranging, the useful Henderson–Hasselbalch form of the dissociation equilibrium equation can be derived:

$$\mathrm{pH} = \mathrm{pKa} + \log\left[HCO_3^-\right] / \left[H_2CO_3\right]$$

Gaseous CO_2 produced in the tissues, primarily via the tricarboxylic acid cycle, is soluble in water; the concentration of dissolved CO_2 in body fluids can be related to the partial pressure of CO_2 in the gas phase, $P\mathrm{CO}_2$, by the following expression:

$$\left[\text{dissolved } CO_2\right] = 0.03 \times P_{CO_2}$$

Hence the clinically useful form of this equation for the bicarbonate–carbonic acid buffer system becomes

$$\mathrm{pH} = 6.1 + \log\left[HCO_3^-\right] / (0.03 \times P_{CO_2})$$

The bicarbonate–carbonic acid system is the most physiologically important extracellular buffer system because it is present in relatively high concentrations in the blood and because it can effectively buffer by rapid regulation of $P\mathrm{CO}_2$ through alveolar ventilation. As carbonic acid is formed from the buffering of excess H^+ by HCO_3^-, this drives the dissociation equation of carbonic acid to the left, causing an increase in $P\text{CO}_2$. An increase in ventilation enhances CO_2 excretion and lowers the $P\text{CO}_2$.

Intracellular buffers also contribute to maintenance of body pH. The primary intracellular buffers are proteins, organic and inorganic phosphates, and, in the red cell, hemoglobin. Hemoglobin is an especially important buffer for carbonic acid since the primary extracellular buffer, the bicarbonate system, cannot buffer this acid. Bone also acts as a tissue-based buffer by exchanging surface Na^+ and K^+ for H^+ under conditions of acid load. Additionally, dissolution of bone mineral results in release of buffer compounds into the ECF.

Regulation of Hydrogen Ion, Carbon Dioxide, and Bicarbonate

Pulmonary and renal control of dissolved CO_2 and bicarbonate concentrations, respectively, is responsible for maintenance of body pH. The "tail" of the Henderson–Hasselbalch equation for the bicarbonate system (i.e., HCO_3^-/dissolved CO_2) provides a simplistic but useful means to consider pulmonary and renal adjustments during simple acid–base disturbances. Under normal physiological conditions, the ratio of HCO_3^- to dissolved CO_2 is 20 : 1. This ratio can be disturbed by addition or loss of CO_2 or bicarbonate to the system. Table 23.10 depicts changes in the tail of the bicarbonate–carbonic acid dissociation equation that might occur during simple acid–base disturbances. The respiratory component of acid–base regulation (the denominator of the tail, or dissolved CO_2) involves changes in respiratory rate and volume prompted by changes in $P\text{CO}_2$. Initiation of these processes requires only minutes.

The renal component of acid–base regulation (the numerator of the tail, or HCO_3^-) involves selective absorption of bicarbonate and secretion of H^+. During periods of acidosis, relatively more H^+ are secreted, while relatively more K^+, Na^+, and HCO_3^- are retained. During alkalosis, K^+ is secreted, while relatively more H^+ and less Na^+ and HCO_3^- are retained. This process requires hours to days to produce an effect. The kidney regulates acid–base balance by maintaining the appropriate HCO_3^- in the plasma. The kidney accomplishes this by reclaiming virtually all filtered HCO_3^- and excreting an amount of acid that equals the amount of ingested or endogenously generated nonvolatile acid. In the proximal tubule of the kidney, cytoplasmic carbonic anhydrase catalyzes the formation of H^+ and bicarbonate from cellular carbon dioxide and water, controlling the rate of hydrogen secretion and bicarbonate reabsorption. In the luminal membrane, carbonic anhydrase converts carbonic acid to carbon dioxide and water, increasing net bicarbonate reabsorption (Figure 23.5A). In the distal nephron, intercalated cells specialized for hydrogen secretion contain large quantities of carbonic anhydrase, again yielding hydrogen and bicarbonate. In this case, secreted H^+ serves to titrate buffers in the urine (phosphate buffering is shown in Figure 23.5B) and lower urinary pH. As titratable acidity of the urine reaches a maximum, another adaptation, increased ammonia (NH_3) production by tubular cells, contributes to excretion of acid loads. Figure 23.5C, shows production of freely

Table 23.10 Examples of changes in the "tail" of the Henderson–Hasselbalch equation occurring during simple acid–base disturbances

Respiratory acidosis (↓ CO_2 elimination) associated with inadequate ventilation:

$$\underset{\text{(Normal)}}{\frac{20\text{HCO}_3^-}{1\text{CO}_2}} + \underset{(\downarrow\ \text{Ventilation})}{2\text{CO}_2} \rightarrow \underset{\text{(Uncompensated)}}{\frac{20\text{HCO}_3^-}{3\text{CO}_2}} + \underset{\text{(Renal production)}}{40\text{HCO}_3^-} \rightarrow \underset{\text{(Compensated)}}{\frac{60\text{HCO}_3^-}{3\text{CO}_2}} = \frac{20}{1}$$

Respiratory alkalosis (↑ CO_2 elimination) associated with hyperventilation:

$$\underset{\text{(Normal)}}{\frac{20\text{HCO}_3^-}{1\text{CO}_2}} - \underset{(\uparrow\ \text{Ventilation})}{0.5\text{CO}_2} \rightarrow \underset{\text{(Uncompensated)}}{\frac{20\text{HCO}_3^-}{0.5\text{CO}_2}} - \underset{\text{(Renal excretion)}}{10\text{HCO}_3^-} \rightarrow \underset{\text{(Compensated)}}{\frac{10\text{HCO}_3^-}{0.5\text{CO}_2}} = \frac{20}{1}$$

Metabolic acidosis (bicarbonate deficit) associated with diarrhea:

$$\underset{\text{(Normal)}}{\frac{20\text{HCO}_3^-}{1\text{CO}_2}} - \underset{\text{(Loss in feces)}}{10\text{HCO}_3^-} \rightarrow \underset{\text{(Uncompensated)}}{\frac{10\text{HCO}_3^-}{2\text{CO}_2}} - \underset{(\text{Eliminated by}\ \uparrow\ \text{ventilation})}{0.5\text{CO}_2} \rightarrow \underset{\text{(Compensated)}}{\frac{10\text{HCO}_3^-}{0.5\text{CO}_2}} = \frac{20}{1}$$

Metabolic alkalosis (bicarbonate excess) associated with administration of alkali:

$$\underset{\text{(Normal)}}{\frac{20\text{HCO}_3^-}{1\text{CO}_2}} + \underset{\text{(Alkali administration)}}{20\text{HCO}_3^-} \rightarrow \underset{\text{(Uncompensated)}}{\frac{40\text{HCO}_3^-}{1\text{CO}_2}} - \underset{(\text{Eliminated by}\ \downarrow\ \text{ventilation})}{1\text{CO}_2} \rightarrow \underset{\text{(Compensated)}}{\frac{40\text{HCO}_3^-}{2\text{CO}_2}} = \frac{20}{1}$$

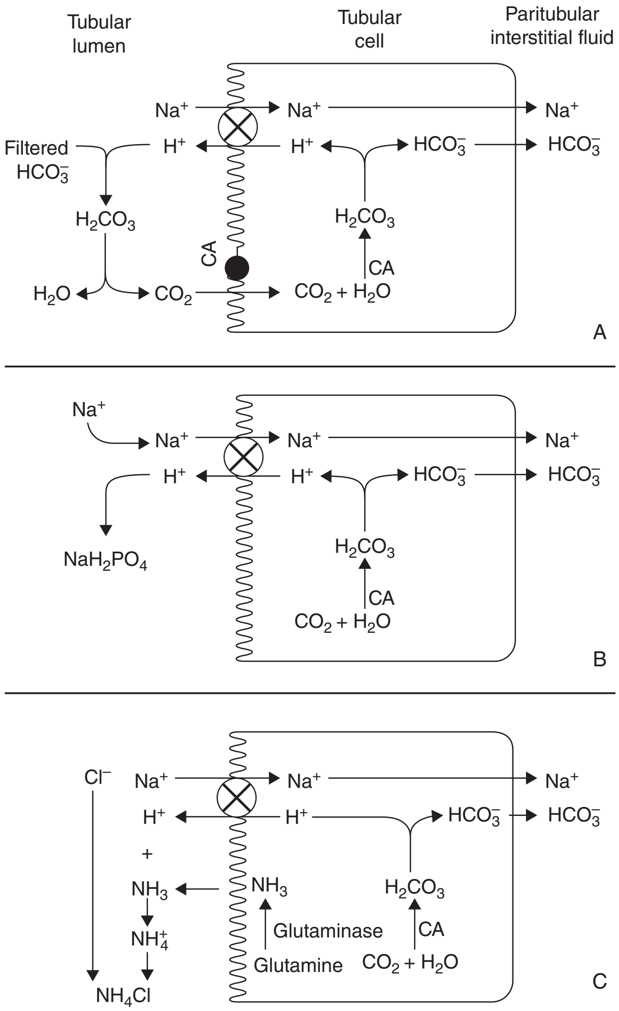


Figure 23.5 Renal mechanisms for H^+ excretion. See text for explanation of each panel.

diffusable NH_3 from glutamine moving into the tubular lumen, where it combines with H^+ to form ammonium (NH_4^+). Ammonium, in turn, combines with chloride for excretion as ammonium chloride. While this is an oversimplification of the physiological events, it is acceptable to consider ammonium chloride as a flexible mechanism for H^+ secretion based on the ability of the kidney to generate ammonia.

Assessment of Acid–Base Disturbances

Disorders of acid–base equilibrium can result from a primary disturbance in pulmonary regulation of the concentration of H_2CO_3 in body fluids via changes in alveolar ventilation and $P\text{CO}_2$ levels, from metabolic changes in concentration of bicarbonate, or from a combination of these mechanisms.

The partial pressure of CO_2 ($P\text{CO}_2$) is generally accepted as the best measure of respiratory disturbances. Assessment of $P\text{CO}_2$ depends upon availability of a blood gas analyzer and proper arterial sample collection. A blood gas analysis provides three measured parameters (pH, $P\text{CO}_2$, $P\text{O}_2$) and typically two calculated values (actual bicarbonate and base excess). Acidemia and alkalemia (using pH), eucapnia, hypercapnia or hypocapnia (using $P\text{CO}_2$), and hypoxemia (using $P\text{O}_2$ if the sample is arterial) may be directly assessed. In-house blood gas and electrolyte analyzers have become much more common in practice, making assessment of these parameters practical and economical. Results obtained with one handheld analyzer appropriate for in-house testing were similar to those obtained from a standard chemistry analyzer with the exception of sodium concentration in canine samples and hematocrit in equine samples (Looney et al., 1998).

Actual bicarbonate values are useful in assessment of nonrespiratory disorders, but these values will vary with compensatory changes in alveolar ventilation and $P\text{CO}_2$. Bicarbonate values are derived using the Henderson–Hasselbalch equation and measured values for pH and $P\text{CO}_2$. Plasma bicarbonate values may also be estimated by measurement of total CO_2. Total CO_2 combines measurement of both the numerator and the denominator of the tail of the Henderson–Hasselbalch equation ($[HCO_3^-]/[H_2CO_3]$) by converting both to measurable CO_2. Total CO_2 and plasma bicarbonate are used interchangeably in reporting plasma bicarbonate concentrations even though total CO_2 is actually plasma bicarbonate plus 1.1–1.3 mEq of H_2CO_3. As compared to actual plasma bicarbonate, standard bicarbonate is defined as the concentration of bicarbonate after fully oxygenated whole blood has been equilibrated with CO_2 at a $P\text{CO}_2$ of 40 mmHg at 38°C; this measurement eliminates the influence of respiration on plasma HCO_3^-.

Standard base excess (BE) is the concentration of titratable base of ECF; this value may be calculated using a Siggaard–Anderson alignment nomogram that interrelates BE and total CO_2 and HCO_3^- when pH and $P\text{CO}_2$ are measured. Because this calculation is based on a constant oxygen saturation, error may be introduced by inclusion of air bubbles in a poorly handled blood sample. In veterinary medicine, error may also be inherent because the nomogram is based on human blood and excludes the effects of plasma protein and electrolytes on acid–base equilibrium. BE is useful because it accounts for the effects of CO_2 on carbonic acid equilibrium and identifies nonrespiratory causes of acid–base derangement. Base deficit is defined as the negative of base excess (Bailey and Pablo, 1998).

Anion Gap

Further analysis, beyond pH, $P\text{CO}_2$, HCO_3^-, and BE, may be useful in assessment of complex acid–base disturbances. The anion gap (AG) is defined as the difference between the quantity of unmeasured cations (UCs) and unmeasured anions (UAs) in the blood. Major UAs include phosphates, sulfates, and organic acids (e.g., lactate, citrate, ketones), with chloride and bicarbonate being the measured anions. Major UCs include calcium and magnesium, with sodium and potassium being the measured cations. Calculation of the AG according to the following equations reflects the law of electroneutrality, according to which total cations must equal total anions (DiBartola, 1992d).

$$[\mathrm{Na}^+] + [\mathrm{K}^+] + [\mathrm{UC}] = [\mathrm{Cl}^-] + [\mathrm{HCO}_3^-] + [\mathrm{UA}]$$

$$\text{Anion gap} = \mathrm{UC} - \mathrm{UA} = ([\mathrm{Na}^+] + [\mathrm{K}^+]) - ([\mathrm{Cl}^-] + [\mathrm{HCO}_3^-])$$

The normal AG varies with the species but is approximately 13–24 mEq/l in dogs and cats. AG is most often used to identify causes of metabolic acidosis. In organic acidoses, $\mathrm{HCO_3}^-$ buffers hydrogen ions that are generated from dissociation of organic acid (e.g., lactic acid). In theory, the measured $[\mathrm{HCO_3}^-]$ should decrease as the concentration of the UA (the organic acid) increases. As long as $[\mathrm{Cl}^-]$ remains unchanged (normochloremic metabolic acidosis), the gap will increase proportionately with the increase in acid. Several factors that may confound this simple relationship include the following: (i) other buffers besides $\mathrm{HCO_3}^-$ also respond to the influx of organic acid; (ii) the volume of distribution of $\mathrm{HCO_3}^-$ may be different from that of the acid; and (iii) the patient's AG baseline (prior to the presenting illness) is often not known. Hence the AG is useful but not fully predictable.

Increased AG often occurs in lactic acidosis, diabetic ketoacidosis, azotemic renal failure (due to increased phosphates and sulfates), and poisoning (ethylene glycol, salicylate). Constable et al. (1997) demonstrated a useful correlation between AG and serum creatinine concentration in calves with experimentally induced diarrhea and adult cattle with abomasal volvulus. Although the AG was not a useful predictor of all anion-associated changes (e.g., no correlation was found between AG and blood lactate levels), the AG could alert clinicians to the potential presence of uremic acidosis.

A normal AG usually occurs in metabolic acidosis related to diarrhea, renal tubular acidosis, excessive use of carbonic anhydrase inhibitors, or ammonium chloride administration and in iatrogenic expansion acidosis caused by excessive normal saline administration. The two most common causes of a decreased AG are hypoalbuminemia or dilution of plasma proteins caused by infusion of crystalloid solutions. In both cases the gap decreases as a result of a decreased concentration of net negative charges associated with plasma proteins. Each 1.0 g/dl decrease in albumin is associated with an approximately 2.4 mEq/l decrease in the AG (Gabow, 1985).

Nontraditional (Stewart's) Acid–Base Analysis

An understanding of the traditional interrelationships between H^+, $\mathrm{CO_2}$, and $\mathrm{HCO_3}^-$ is adequate to explain the behavior of aqueous solutions; however, it does not account for the effects of plasma proteins and electrolytes, particularly sodium and chloride, on acid–base status in biological systems. Stewart described a new approach to understanding acid–base physiology based on three fundamental concepts of electrolyte chemistry (Stewart, 1978, 1983). First, electroneutrality must always be maintained. Hence, as with the concept of the AG, the sum of all positive charges must equal the sum of all negative charges. Second, mass must be conserved even though it may change in form within a solution. Finally, the dissociation or ionization of a substance in water is determined by its dissociation constant. Weak electrolytes relevant to acid–base physiology include proteins, water, and $\mathrm{CO_2}$. In contrast, sodium and chloride are considered strong electrolytes because they are fully dissociated in water. Evaluation of acid–base status using the Stewart approach requires assessment of independent, or primary, variables; dependent, or unknown, variables; and dissociation constants of all variables. Values of independent variables are controlled externally and cannot be changed by processes occurring within the solution. Independent variables dictate the acid–base status of a solution.

The independent variables controlling acid–base status in biological solutions are strong ion difference (SID), $P\mathrm{CO_2}$, and total weak acid concentration ($\mathrm{A_{TOT}}$). The first variable, SID, is the sum of the strong cation concentrations minus the sum of the strong anion concentrations:

$$\mathrm{SID} = ([\mathrm{Na}^+] + [\mathrm{K}^+]) - ([\mathrm{Cl}^-] + [\text{lactate}^-] + [\text{ketoacid}])$$

Unless lactic acidosis or ketoacidosis is suspected in a given case, these terms may be eliminated from the equation since their values would be quite small. Likewise, $[\mathrm{K}^+]$ is often dropped from the equation since it contributes a relatively small number to the total cation population. If $P\mathrm{CO_2}$ and $\mathrm{A_{TOT}}$ remain constant, increases in SID suggest nonrespiratory alkalosis and decreases suggest nonrespiratory acidosis. Mean normal SID values are derived by each laboratory based on their reference population, and these values vary across species. The second independent variable, $P\mathrm{CO_2}$, is an indication of the amount of $\mathrm{CO_2}$ dissolved in plasma. As in traditional acid–base theory, an increase in $P\mathrm{CO_2}$ shifts the dissociation equation for carbonic acid to the right, increasing the $[\mathrm{H}^+]$ and making the solution more acidic. The final independent variable, $[\mathrm{A_{TOT}}]$, is accounted for by plasma proteins (95%), primarily albumin, and inorganic phosphates (5%). $\mathrm{A_{TOT}}$ has been calculated for horses (Constable, 1997) using the formula

$$[\mathrm{A_{TOT}}]\ (\mathrm{mEq/l}) = 2.25\ [\mathrm{albumin}]\ (\mathrm{g/dl}) + 1.4\ [\mathrm{globulin}]\ (\mathrm{g/dl}) + 0.59\ [\mathrm{phosphate}]\ (\mathrm{mg/dl})$$

These three independent variables influence several dependent, or unknown, variables. Dependent variables are affected by processes occurring within the solution and do not change unless independent variables change. Values for dependent variables are thus the result, not the cause, of events in solution. Dependent variables include $[\mathrm{H^+}]$, $[\mathrm{HCO_3^-}]$, carbonate ion concentration ($[\mathrm{CO_3^{2-}}]$), $[\mathrm{OH^-}]$, concentration of dissociated weak acids ($[\mathrm{A^-}]$), and concentration of nondissociated weak acids ([AH]). Values of dependent variables are not affected by the values of other dependent variables. Because the values for $[\mathrm{CO_3^{2-}}]$ and $[\mathrm{OH^-}]$ are so small, they are not measured or evaluated in a clinical setting. The variables for dissociated and nondissociated weak acids reflect the dynamic relationship between acid–base balance and protein ionization. The ability of proteins to function as enzymes, cell membrane pumps, ion channels, receptors, etc., depends upon their state of ionization, and this is directly affected by changes in independent variables ($P\mathrm{CO_2}$, SID, and $\mathrm{A_{TOT}}$). Likewise, the ratio of ionized to unionized calcium depends upon protein binding, which changes with alterations of $\mathrm{A_{TOT}}$ and pH.

Independent variables are controlled via respiration ($P\mathrm{CO_2}$) and renal function (SID). As in traditional acid–base theory, rate and depth of respiration control retention or elimination of $\mathrm{CO_2}$, which may lead to respiratory acidosis or alkalosis, respectively. Control of SID is primarily accomplished by the kidney with a smaller contribution from the gastrointestinal tract. Changes in SID via the kidneys are achieved much more slowly than respiratory changes and are on the order of hours to days. The kidney regulates SID by differential reabsorption of $\mathrm{Na^+}$ and $\mathrm{Cl^-}$. Since $\mathrm{Na^+}$ reabsorption is strongly related to renal regulation of ECF volume, net $\mathrm{Cl^-}$ excretion relative to net $\mathrm{Na^+}$ excretion is the primary mechanism for renal regulation of acid–base balance. Control of $P\mathrm{CO_2}$ and SID is the primary determinant of acid–base balance because there is no evidence that the body alters the third independent variable, protein concentration $[\mathrm{A_{TOT}}]$, in order to regulate acid–base balance.

In summary, the most important premise of Stewart's approach is that concentrations of $\mathrm{HCO_3^-}$ and $\mathrm{H^+}$ are dependent on concentrations of primary, or independent, variables, notably $\mathrm{CO_2}$, $\mathrm{Na^+}$, and $\mathrm{Cl^-}$. The complex equations derived by Stewart address the changes induced by independent variables and quantitate each potential influence by solving for the dependent variables. Much simplified versions of Stewart's formula have been adopted on a limited basis by clinicians who value Stewart's theories and believe that they provide a more complete picture of acid–base derangements. Table 23.11 summarizes the equations being applied for nontraditional analysis of nonrespiratory acid–base status (Russell et al., 1996). In brief, increases in SID suggest nonrespiratory alkalosis, whereas decreases suggest nonrespiratory acidosis. Negative values for Δ albumin suggest hyperproteinemic acidosis, whereas positive values reflect hypoproteinemic alkalosis. Negative values for Δ phosphorus suggest hyperphosphatemic acidosis. Negative changes in free water point to dilutional acidosis, and positive values suggest concentration alkalosis. Positive values for Δ chloride suggest hypochloremic alkalosis, and negative values suggest hyperchloremic acidosis.

Table 23.11 Formulas for quantitative analysis of nonrespiratory acid–base status

I. Estimation of [SID] (all values expressed as mEq/l)
   $[\mathrm{SID\ approx.}] = [\mathrm{Na^+}_{\mathrm{mean\ normal}}] - [\mathrm{Cl^-}_{\mathrm{corrected}}]$
   $[\mathrm{Cl^-}_{\mathrm{corrected}}] = [\mathrm{Cl^-}_{\mathrm{patient}}] \times ([\mathrm{Na^+}_{\mathrm{mean\ normal}}] / [\mathrm{Na^+}_{\mathrm{patient}}])$
II. Alterations in acid–base balance
   A. Changes in acid–base balance due to weak acids
      Δ albumin (mEq/l) $= 3.7 \times ([\mathrm{alb}_{\mathrm{mean\ normal}}]\ (\mathrm{mg/dl}) - [\mathrm{alb}_{\mathrm{patient}}]\ (\mathrm{mg/dl}))$
      Δ phosphorus:
         $[\mathrm{phos}_{\mathrm{adjusted}}]\ (\mathrm{mg/dl}) = [\mathrm{phos}_{\mathrm{mean\ normal}}]\ (\mathrm{mg/dl}) - [\mathrm{phos}_{\mathrm{patient}}]\ (\mathrm{mg/dl})$
         $\mathrm{phos}_{\mathrm{adj}}\ (\mathrm{mg/dl}) \times 0.3229 = \mathrm{phos}\ (\mathrm{mmol/l})$
         effective phos (mEq/l) $= 1.8 \times$ phos (mmol/l)
   B. Changes in acid–base balance due to alterations in [SID] (all values expressed in mEq/l)
      Δ free water $= z([\mathrm{Na^+}_{\mathrm{patient}}] - [\mathrm{Na^+}_{\mathrm{mean\ normal}}])$
         where $z = [\mathrm{SID}] / [\mathrm{Na^+}_{\mathrm{mean\ normal}}]$
      Δ chloride $= [\mathrm{Cl^-}_{\mathrm{mean\ normal}}] - [\mathrm{Cl^-}_{\mathrm{corrected}}]$
      Δ unmeasured anions (UA) = BE − (Δ free water + Δ $\mathrm{Cl^-}$ + Δ phos + Δ albumin)

BE, base excess; SID, strong ion difference; UA, unmeasured anions.

While most clinicians still favor the traditional approach to evaluation of acid–base balance, modified applications of Stewart's theories broaden this scope and lend useful quantitative insights into the complexities of acid–base disturbances (Constable, 1999).

Disorders of Acid–Base Metabolism

Disorders of acid–base equilibrium can result from a primary disturbance in pulmonary regulation of the concentration of $\mathrm{CO_2}$, from metabolic changes in strong ions and, dependently, bicarbonate, or from a combination of these mechanisms. An acid–base disturbance is considered simple if it is limited to a primary disturbance and an appropriate secondary or compensatory response. Primary disturbances and expected compensatory responses are modeled using the tail of the Henderson–Hasselbalch equation in Table 23.10 and summarized in Table 23.12. Mixed acid–base disturbances are suspected

Table 23.12 Characteristics of primary acid–base disturbances. Source: Adapted from Rose, 1994.

Disorder	pH	[H+]	Primary disturbance	Compensatory response
Metabolic acidosis	↓	↑	↓ $[HCO_3^-]$, ↓ [SID]	↓ $P\text{CO}_2$
Metabolic alkalosis	↑	↓	↑ $[HCO_3^-]$, ↑ [SID]	↑$P\text{CO}_2$
Respiratory acidosis	↓	↑	↑ $P\text{CO}_2$	↑ $[HCO_3^-]$, ↑ [SID]
Respiratory alkalosis	↑	↓	↓ $P\text{CO}_2$	↓ $[HCO_3^-]$, ↓ [SID]

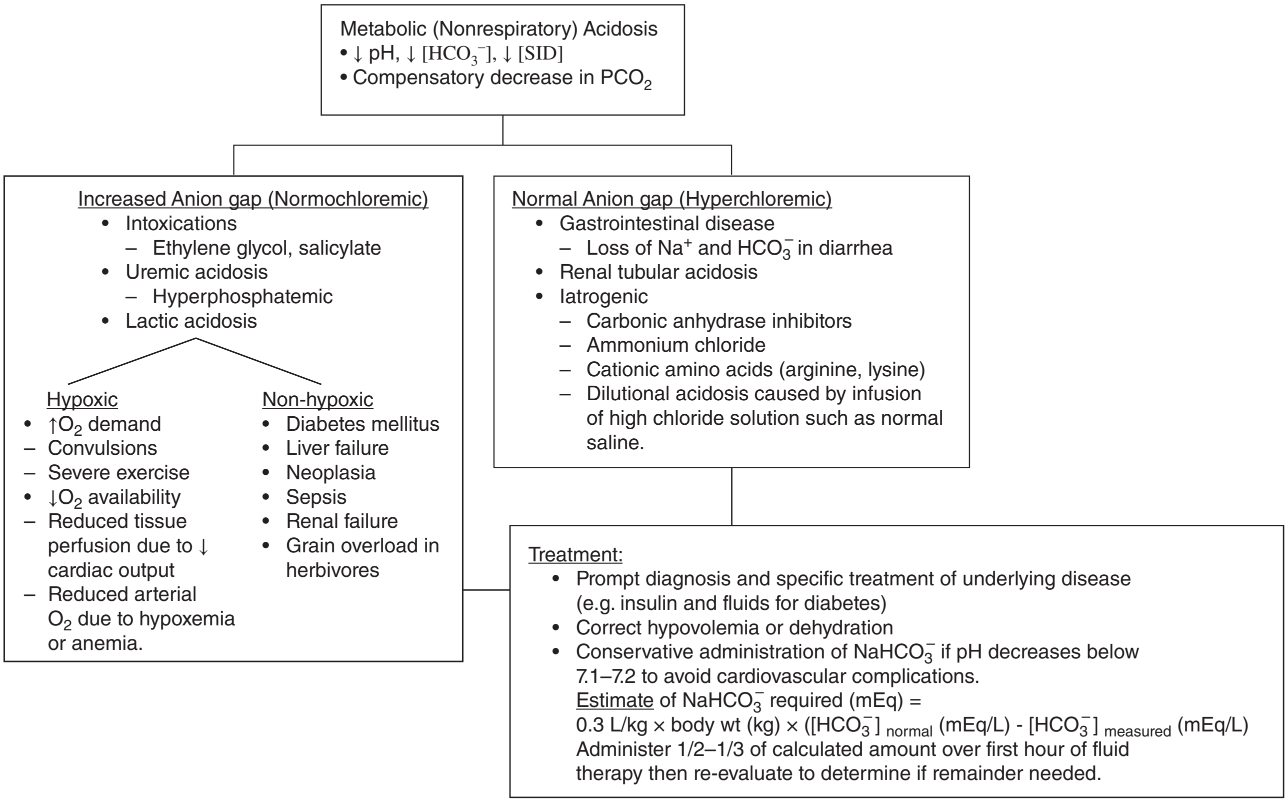
SID, strong ion difference.

when the compensatory response to a primary disorder is not as expected or when the pH is changing in a direction opposite that predicted by the primary disorder. Mixed acid–base disturbances are characterized by two or more primary disturbances in the same patient.

Metabolic (Nonrespiratory) Acidosis

Metabolic acidosis may be characterized by a decrease in plasma HCO_3^- concentration, decreased pH, increased concentration of strong anions (such as chloride, lactic acid, or ketoacids), and decreased plasma sodium concentration associated with renal disease or diarrhea. The clinical signs most commonly associated with metabolic acidosis are hyperpnea and CNS depression. Laboratory analysis of blood and urine reveals a lowered urine and blood pH, decreased serum HCO_3^- (<20 mEq/l), decreased [SID], and a variable serum $P\text{CO}_2$ depending upon the degree of respiratory compensation. Figure 23.6 summarizes causes of metabolic acidosis and provides general principles of treatment. Metabolic acidosis is the most common acid–base disorder in dogs, cats, and horses, and causes may be usefully subdivided into those conditions that increase the AG and those that do not.

Loss of Na^+ and HCO_3^- associated with diarrhea is the most common cause of normal AG (hyperchloremic) metabolic acidosis. Intestinal secretions replete in Na^+ and HCO_3^- may also be sequestered in lower obstructive bowel disease and paralytic ileus. Hypoadrenocorticism may also present with a nongap metabolic acidosis, but these patients usually have hypochloremia as a result of impaired water excretion, lack of aldosterone, and poor renal function.



Metabolic (Nonrespiratory) Acidosis
- ↓ pH, ↓ $[HCO_3^-]$, ↓ [SID]
- Compensatory decrease in PCO_2

Increased Anion gap (Normochloremic)
- Intoxications
  - Ethylene glycol, salicylate
- Uremic acidosis
  - Hyperphosphatemic
- Lactic acidosis

Hypoxic
- ↑O_2 demand
  - Convulsions
  - Severe exercise
- ↓O_2 availability
  - Reduced tissue perfusion due to ↓ cardiac output
  - Reduced arterial O_2 due to hypoxemia or anemia.

Non-hypoxic
- Diabetes mellitus
- Liver failure
- Neoplasia
- Sepsis
- Renal failure
- Grain overload in herbivores

Normal Anion gap (Hyperchloremic)
- Gastrointestinal disease
  - Loss of Na^+ and HCO_3^- in diarrhea
- Renal tubular acidosis
- Iatrogenic
  - Carbonic anhydrase inhibitors
  - Ammonium chloride
  - Cationic amino acids (arginine, lysine)
  - Dilutional acidosis caused by infusion of high chloride solution such as normal saline.

Treatment:
- Prompt diagnosis and specific treatment of underlying disease (e.g. insulin and fluids for diabetes)
- Correct hypovolemia or dehydration
- Conservative administration of $NaHCO_3^-$ if pH decreases below 7.1–7.2 to avoid cardiovascular complications.

  Estimate of $NaHCO_3^-$ required (mEq) =

  $0.3\ \text{L/kg} \times \text{body wt (kg)} \times ([HCO_3^-]_{\text{normal}}\ (\text{mEq/L}) - [HCO_3^-]_{\text{measured}}\ (\text{mEq/L})$

  Administer 1/2–1/3 of calculated amount over first hour of fluid therapy then re-evaluate to determine if remainder needed.

Figure 23.6 Causes of metabolic acidosis and general treatment principles.

Lactic Acidosis

Production of lactic acid and accumulation of lactate, an unmeasured anion, decrease the [SID], resulting in a high AG metabolic acidosis. Lactic acid is the final product of anaerobic glycolysis in eukaryotic cells and is formed by the action of lactate dehydrogenase (LDH) on pyruvic acid with NADH as a cofactor.

$$\mathrm{CH_3COO^- + NADH + H^+ CH_3CHOHCOO^-} \\ \mathrm{+ NAD^+(pyruvate)LDH(lactate)}$$

The direction of the LDH reaction depends upon the relative intracellular concentrations of pyruvate and lactate and on the ratio of reduced (NADH) to oxidized (NAD^+) nicotinamide adenine dinucleotide cofactor. Newly produced lactic acid is partially buffered by HCO_3^-, resulting in rapid generation of sodium lactate, which dissociates to lactate and sodium ions. Under aerobic conditions in the liver and the kidney, lactate is converted back to pyruvate, and pyruvate is metabolized through the tricarboxylic acid (TCA) cycle to yield HCO_3^-, CO_2, and H_2O. Alternatively, hepatic uptake of lactate and conversion to pyruvate can feed gluconeogenesis, a process that also regenerates HCO_3^-. In either case, the net result of aerobic lactate metabolism is production of alkalinizing equivalents in the form of HCO_3^-:

Conversion via the TCA cycle

$$\mathrm{lactate^- + 3O_2 \rightarrow HCO_3^- + 2CO_2 + 2H_2O}$$

Conversion via gluconeogenesis

$$\mathrm{2\ lactate^- + 2H_2O + 2CO_2 \rightarrow 2HCO_3^- + glucose}$$

If the ratio of $NADH/NAD^+$ in the cell shifts toward accumulation of NADH (e.g., in exercising muscle or poorly oxygenated tissues), more lactic acid accumulates, decreasing cellular pH. In the case of poorly oxygenated tissues, inability to oxidize NADH via the respiratory chain blocks oxidative phosphorylation and production of ATP. ATP depletion in lactic acidosis causes leaky ATP-dependent K^+ channels, leading to hyperpolarized membranes and decreased Ca^{++} influx via voltage-dependent Ca^{++} channels. Decreased intracellular Ca^{++} produces smooth muscle relaxation, vasodilation, and a potential decline in systemic blood pressure (Landry and Oliver, 1992).

Causes of the two types of lactic acidosis, hypoxic (type A) and nonhypoxic (type B), are listed in Figure 23.6. (Only L-lactate is metabolized by animals; hence the discussion that follows refers only to L-lactic acidosis and not D-lactic acidosis, a condition described in humans and associated with small bowel resection or short bowel syndrome.) Reduced tissue perfusion and hypoxia caused by cardiac arrest/cardiopulmonary resuscitation, shock, hypovolemia, left ventricular failure, low cardiac output, and acute pulmonary edema limit oxygen availability and force cells into anaerobic glycolysis. As NADH accumulates, the LDH reaction is pushed to the right, resulting in lactic acid accumulation. Successful management of most of these conditions involves returning tissue perfusion and oxygenation to normal, often with the aid of parenteral fluid administration. Reversal of circulatory failure decreases further lactate accumulation and, if the liver is well perfused, will result in conversion of accumulated lactate to HCO_3^-.

Administration of $NaHCO_3^-$ to animals suffering from lactic acidosis is controversial. Benefits could include improved tissue perfusion related to reversal of acidemia-induced vasodilation and an increase in [SID] (associated with Na^+ administration). Potential risks include overshoot metabolic alkalosis caused by the cumulative effect of $NaHCO_3^-$ administration and metabolism of the accumulated lactate into HCO_3^-. A study in rats (Halperin et al., 1996) concluded that $NaHCO_3^-$ therapy extended the period of survival during acute, hypoxic L-lactic acidosis. Hypoxia was induced in anesthetized, paralyzed rats ventilated with a lowered (5.5%) oxygen concentration, which was sufficient to cause a severe degree of L-lactic acidosis. Survival in rats receiving $NaHCO_3^-$ was close to twofold longer than in rats receiving no sodium bicarbonate or NaCl only. The rate of $NaHCO_3^-$ infusion was titrated to equal the rate of L-lactic acid appearance in the ECF of control hypoxic rats. Part of the benefit of alkali treatment was hypothesized to be increased anaerobic glycolysis, causing enhanced ATP and L-lactic acid production and a decreased oxygen consumption. Despite continued accumulation of L-lactic acid and a decrease in cardiac output that was greater than in control rats, availability of ATP for vital organs was considered critical to prolonged survival in alkali-treated animals. While results using this controlled model are not directly clinically applicable, they suggest that continued consideration of the advantages and disadvantages of alkali supplementation in L-lactic acidosis may be merited. Many clinicians favor a conservative therapeutic approach in which small amounts of $NaHCO_3^-$ are administered to keep the arterial pH above 7.1–7.2 and to avoid progressive decline in cardiovascular function (Rose, 1994). In the absence of severely elevated concentrations of lactate, and in the presence of a well-perfused liver, the use of lactate-containing alkalinizing solutions is effective for volume restoration. Alternatives to lactate-containing solutions include $NaHCO_3^-$, sodium gluconate, and sodium acetate.

Ketoacidosis and Other Causes

Metabolic acidosis associated with ketonemia and ketonuria occurs when the rate of formation of ketone bodies is greater than the rate of their use. This occurs most often in two conditions, diabetes mellitus and starvation. Excess acetyl coenzyme A (CoA) derived from fatty acid or pyruvate oxidation is diverted, primarily in the liver, to production of ketone bodies (acetoacetate, β-hydroxybutyrate, acetone). Ketones can be transported in the blood and utilized as an energy source by peripheral tissues. In diabetes the lack of insulin increases lipolysis, and an excess of glucagon indirectly increases fatty acetyl CoA entry into hepatic mitochondria for conversion to ketones. An elevation of ketones in the blood results in acidemia because the carboxyl group of the ketone body has a pK_a of about 4. At physiological pH the ketoacid is fully dissociated, losing a proton (H^+), which lowers blood pH. Addition of an unmeasured anion, the ketoacid, decreases the [SID] driving an acidosis. Ketoacidosis is often complicated by dehydration associated with osmotic (glucose-driven) diuresis. The use of alkali to treat diabetic ketoacidosis is controversial and not generally recommended. Rehydration (usually with normal saline) and administration of insulin is the treatment of choice since circulating ketoacids will subsequently be metabolized to HCO_3^- and move plasma pH toward normal.

Renal failure typically produces a normochloremic, high-AG metabolic acidosis due to accumulation of phosphates, sulfates, and other organic anions, altered handling of chloride, and an inability to excrete the daily dietary acid load. Enhanced generation of ammonia by the renal tubular cells allows the kidney to respond, up to a point, to the chronic retention of fixed acid. Use of alkali to treat metabolic acidosis associated with renal failure is controversial. Three reasons cited in support of treatment are that treatment (i) spares depletion of bone serving as a H^+ buffer, (ii) prevents the potentially catabolic effects of acidosis on muscle protein, and (iii) limits complement-mediated tubulointerstitial damage that may occur in concert with increased ammoniagenesis. Oral administration of $NaHCO_3^-$ (0.5–1.0 mEq/kg/day) with the goal of maintaining plasma HCO_3^- at 15 mEq/l may be effective if the associated sodium load does not encourage fluid retention.

Metabolic (Nonrespiratory) Alkalosis

Metabolic alkalosis is characterized by an excess of HCO_3^- caused by a deficit of H^+ in the ECF. This state may be caused by excessive vomiting (especially from gastrointestinal obstruction), excessive alkaline therapy, or use of diuretics that can create iatrogenic metabolic alkalosis, or excessive loss of potassium caused by hyperadrenocorticism or administration of large quantities of K^+-free solutions. Clinical signs of metabolic alkalosis are depressed breathing (slow and shallow), nervous excitement, including tetany, and even convulsions and muscular hypertonicity. Respiratory compensation is not as effective as respiratory compensation for metabolic acidosis.

Values for serum electrolytes usually reveal elevated [HCO_3^-], lowered [Cl^-], and variable [Na^+]. There is usually a low serum [K^+] in this condition. A relationship exists between K^+ loss and metabolic alkalosis in that each can result in the other (positive feedback). In ruminants the situation is much more complex, and unlike in small animals, metabolic alkalosis is much more common. Compensation for metabolic alkalosis requires the kidneys to excrete HCO_3^- and retain H^+. Therapy for metabolic alkalosis involves treatment of the underlying disease and, potentially, use of acidifying solutions such as NaCl (0.9%), NH_4Cl (1.9%) (NH_3^+ is conjugated to urea in the liver, which frees H^+ and Cl^-), and Ringer's solution, which supplies Na^+, K^+, Ca^{++}, and Cl^-.

Respiratory Acidosis

Respiratory acidosis (Table 23.13) involves retention of CO_2 as a consequence of alveolar hypoventilation. The fall in pH is predictable from the Henderson–Hasselbalch equation. Impaired respiration can be

Table 23.13 Causes of respiratory acidosis. Source: Adapted from DiBartola, 1992a. Reproduced with permission of Elsevier.

- Inadequate mechanical ventilation
- Airway obstruction

  - Respiratory distress syndrome
  - Pneumonia
  - Severe pulmonary edema
  - Diffuse metastatic disease
  - Smoke inhalation
  - Pulmonary thromboembolism
  - Chronic obstructive pulmonary disease
  - Pulmonary fibrosis

caused by pneumonia, pulmonary edema, emphysema, pneumothorax, respiratory muscle paralysis, morphine, barbiturate, or anesthetic poisoning, airway occlusion, or, most commonly, hypoventilation during positive pressure ventilation (iatrogenic). Clinical signs include respiratory distress and CNS depression with progressive disorientation, weakness, and finally coma (CO_2 narcosis). Cyanosis is often present in the advanced stages. Laboratory analysis of blood and urine will show a decreased urine pH, decreased blood pH, increased serum HCO_3^- (from tissue buffers and renal reabsorption of HCO_3^-), and a decrease in serum Cl^- because of renal excretion. Hypoventilation results in CO_2 retention, an excess of H_2CO_3, and thereby an excess of H^+. The compensatory mechanism is for the kidneys to conserve HCO_3^- and excrete H^+. The most important treatment for this condition is proper ventilation of the animal. Use of alkalinizing solutions may aid in cases of lung disease when ventilation alone will not correct the condition. Whenever possible, therapy should be directed at removal of the causative factor.

Respiratory Alkalosis

Causes of respiratory alkalosis are indicated in Table 23.14. The most common cause of this disease in animals is overactive positive pressure ventilation during anesthesia (iatrogenic). Other causes include fever, stimulation of respiratory centers by encephalitis, salicylate intoxication, a deficiency of O_2 (hypoxia), heat prostration, or conditions causing chronic hyperventilation (excessive blowing off of CO_2). Clinical signs include hyperpnea (with or without panting), hyperactive tendon reflexes, and CNS stimulation with or without convulsions. Laboratory analysis reveals increased urine pH, increased blood pH, and decreased serum HCO_3^-. Serum Cl^- is usually normal to slightly increased, and pathogenesis of the condition relates to excessive blowing off of CO_2. Compensation occurs by renal excretion of HCO_3^- and retention of H^+. Treatment for this condition should involve correcting the hyperventilation, when feasible, and use of the same acidifying solutions used for metabolic alkalosis. Underlying etiological factor(s) must be eliminated.

Table 23.14 Causes of respiratory alkalosis. Source: Adapted from DiBartola, 1992a. Reproduced with permission of Elsevier.

- Overzealous mechanical ventilation
- Hypoxemia (stimulation of peripheral chemoreceptors by decreased oxygen delivery):
  - Right-to-left shunts
  - Decreased Po_2 (e.g., high altitude)
  - Congestive heart failure
  - Severe anemia
  - Hypotension
  - Pulmonary diseases resulting in ventilation–perfusion mismatching:
  - Pneumonia
  - Pulmonary embolism
  - Pulmonary fibrosis
  - Pulmonary edema
  - Pulmonary disease resulting in stimulation of nociceptive receptors independent of hypoxemia:
  - Pneumonia
  - Pulmonary embolism
  - Interstitial lung disease
  - Pulmonary edema
- CNS-mediated hypocapnia with direct stimulation of medullary respiratory center:
  - Liver disease
  - Gram-negative sepsis
  - Drugs (e.g., salicylate intoxication, progesterone, xanthines)
  - Recovery from metabolic acidosis
  - Central neurological disease
  - Heat stroke

Mixed Acid–Base Disturbances

The preceding discussion of acidosis and alkalosis has purposely dealt with idealized, single etiological processes in the genesis of acid–base abnormalities. Such states rarely exist in real life. Mixed disturbances usually occur, and treatment will often convert one type of acid–base disturbance into another. Proper therapy must include careful appraisal of repeated laboratory determinations and close observation of the clinical situation. Using these techniques, mixed disturbances can be identified, evaluated, and managed successfully. Examples of potential causes of mixed respiratory and metabolic disorders are noted in Table 23.15.

Practical Aspects of Fluid Therapy

Diagnosis and Monitoring

When fluid therapy is under consideration, the practitioner must ask the following six questions: (i) When should fluid therapy be instituted? (ii) What kind(s) of solution(s) should be used? (iii) How much fluid should be administered? (iv) How fast should the solution be given? (v) What route of administration should be used? (vi) How will the success of the therapy be evaluated? The answers to these questions are individual in nature and are critically dependent on a knowledge and understanding of normal homeostatic mechanisms. They are also dependent on the history of the patient, a basic understanding of how a particular disease affects water and electrolyte balance, and a correct diagnosis.

The purpose of fluid and electrolyte therapy is to correct dehydration or overhydration and electrolyte imbalance and/or acid–base imbalance. It may also be indicated to correct a condition of acidosis or alkalosis,

  - Septic shock
  - Salicylate toxicity
  - Heat stroke
  - Gastric dilatation volvulus
  - Liver disease (renal tubular acidosis and impaired metabolism of lactate)
  - Lactic acidosis with excessive hyperventilation
  - Pulmonary edema
  - Parvovirus gastroenteritis and septicemia
  - Severe exercise
  - Acute tumor lysis syndrome
  - Cardiopulmonary resuscitation
- Respiratory alkalosis and metabolic alkalosis
  - Gastric dilatation volvulus
  - Hyperadrenocorticism with pulmonary thromboembolism
  - Ventilator-induced mixed alkalosis (too rapid correction of abnormal arterial $P\text{CO}_2$)
  - Congestive heart failure and diuretics
  - Hepatic disease and diuretics
  - Vomiting or hypoproteinemia
  - Parvovirus gastroenteritis and septicemia

treat shock, give parenteral nourishment, or even stimulate organ function (i.e., the kidneys). Causes of fluid, electrolyte, and/or protein loss include situations wherein substances are not available because of lack of supply or condition of the animal; for example, an animal with a fractured mandible may be unable to take in food or liquid, or an animal with a CNS disturbance may be unable to eat or drink because of the primary disease state. Other causes of fluid, electrolyte, and/or protein imbalances may involve excessive elimination.

The following information must be acquired by questioning the owner, observation of the patient, and/or clinical examination: duration and frequency of vomiting and/or diarrhea, consistency of stools, frequency of urination, color of urine, presence and character of thirst, fluid and dietary intake, dryness or elasticity (turgor) of the skin, nature and color of the mucous membranes and sclera, presence of excessive salivation or panting, odor of the breath, and weight loss or gain.

In combination with clinical signs, laboratory examination of the blood provides a rational basis for estimating patient fluid and electrolyte needs and monitoring treatment success. Measurements should include hematocrit, plasma protein, blood gases ($P\text{O}_2$, $P\text{CO}_2$, base excess, HCO_3^-, or total CO_2) and electrolytes (Na^+, K^+, Cl^-), blood urea nitrogen, and creatinine. Because red blood cells and plasma protein are largely limited to the vascular space, the concentration of both tends to increase with dehydration. It is best to assess both hematocrit and plasma protein since results of one or the other test alone can be misleading if preillness values are out of the normal range. For example, preexisting anemia, hypoproteinemia, or physiological events such as splenic contraction can confound interpretation of either parameter if considered alone.

Collection, measurement, and analysis of urine are important for proper care of the critically ill patient. Urinalysis should include tests for specific gravity, glucose, acetone, pH, and albumin and microscopic sediment examination. During a state of dehydration, if the kidneys are functioning normally, specific gravity will increase and urine volume will decrease. If the specific gravity of urine is unchanged or lowered and the animal shows clinical signs of dehydration, the kidneys are probably not functioning properly, and more sophisticated renal function tests must be employed. Specific gravity of urine should be monitored during the treatment period. A decrease in this parameter indicates that hydration is taking place. If the animal has not yet received treatment with a solution containing glucose and it is found in the urine, diabetic acidosis is possibly the cause of dehydration. The urine glucose should also be monitored during treatment. If the animal is receiving glucose and the urine glucose reaches $^+3$ or $^+4$, the dosage must be lowered. Acetone in the urine is a frequent finding during dehydration and/or carbohydrate starvation. If the pH of the urine in species with normally acid urine tests alkaline, a diagnosis of alkalosis may be indicated if no kidney or urinary tract disease is present. The presence of urinary albumin and sediment may be an indication of renal disease. If the kidneys are functioning properly, they can adjust markedly to insult. However, in the presence of renal impairment, therapy must be specific or the treatment may be fatal.

Diligent assessment of clinical signs and laboratory parameters is essential to successful diagnosis and monitoring of fluid and electrolyte imbalances. Useful parameters are summarized in Table 23.16.

Fluid Volume and Type

A standard approach to estimating fluid volume needs should be used. Replacement of adequate volume is often the single most important key to improved clinical status

Table 23.16 Parameters to be monitored during fluid therapy. Source: Adapted from DiBartola, 1992a. Reproduced with permission of Elsevier.

- Normal bronchovesicular lung sounds on auscultation
  - Packed-cell volume
  - Total protein
  - Electrolytes: Na^+, Cl^-, Ca^{2+}, HCO_3^-
  - Arterial pH
  - Arterial $P\text{CO}_2$
  - Urine output
  - Body weight
  - Hemodynamics
    - Central venous pressure
    - Pulmonary capillary wedge pressures
    - Mean arterial pressure
    - Mean pulmonary arterial pressure

of animals with multiple fluid and electrolyte disturbances. Volume replacement should have three specific aims: correct existing deficits, satisfy maintenance needs, and replace continuing loss. Initial volume deficits are addressed by administration of replacement fluids. Calculation of the amount of fluid needed is based on clinical and laboratory assessment of percent of dehydration. See Table 23.5 for a summary of signs correlated to degree of dehydration. The volume needed to address the initial deficit is estimated according to the following equation:

$$\text{Replacement volume (l)} = \text{body weight (kg)} \times \%\ \text{dehydration}$$

Clinicians working with both small and large animals should become comfortable with the large differences in volume that will be required to address deficits in different animals. For example, the replacement volume needed to address an 8% fluid deficit in a dehydrated mare weighing 500 kg is 100 times greater than that needed for a similarly dehydrated cat weighing 5 kg. Forty liters of fluid would initially be administered to the mare versus 400 ml to the cat. In general, the composition of replacement fluids should reflect the composition of the volume of fluid lost. For example, if the volume deficit is related to loss of electrolyte-rich gastrointestinal fluid, then a balanced replacement solution containing Na^+, K^+, Cl^-, and bicarbonate equivalents would likely be selected. Table 23.17 details the compositions of commonly utilized replacement fluids.

Table 23.17 Composition of selected fluid therapy solutions

		Characteristics		Ion composition (mEq/l)						
Type	**Solution**	**pH**	**Osmolarity (mOsm/l)**	**Na^+**	**K^+**	**Cl^-**	**Ca^{++}**	**Mg^{++}**	**Glucose (g/l)**	**Alkalinizing equivalents (mEq/l)**
Replacement

	14.9% KCl	—	4000	0	2000	2000	0	0	0	0

BES, balanced electrolyte solution.

In addition to replacing existing deficits, maintenance fluid needs must be calculated. Maintenance fluids are needed when a patient does not voluntarily ingest sufficient food and water to replace normal losses occurring via urine, feces, respiratory tract, and skin. The average resting animal at standard conditions of humidity and temperature has a rather constant rate of water turnover. For practical purposes, 40–65 ml/kg/24 h (30 ml/lb/day is often used as a rule of thumb) for mature animals and 130 ml/kg/24 h for immature animals serve as average water turnovers for all mammalian species. Based on these assumptions, an average mature dog weighing 20 kg requires about 1.3 l for a daily maintenance supply of water, while a horse weighing 450 kg would require about 29 l/day. Maintenance needs may be modified under conditions of severe stress or fever, extreme environmental conditions, or in the presence of various disease processes. Older animals may need more or less maintenance volume depending upon the presence of polyuria or compromised cardiovascular function, respectively. Administration of various drugs (e.g., glucocorticoids, diuretics) will also affect maintenance needs. The electrolyte composition of fluids used for maintenance differs from that of replacement fluids used to address initial deficits. Because of the composition of fluid lost daily in urine and as insensible loss from the skin and respiratory tract, maintenance fluids are typically lower in sodium (approximately 40 mEq/l) and higher in potassium (approximately 10–16 mEq/l) than replacement fluids. Table 23.17 details the composition of both commercial maintenance fluids and maintenance fluids that can be prepared using other commonly available fluid components. In veterinary medicine, in contrast to human medicine, patients are less often transitioned from replacement to maintenance fluids. Consequently, veterinary hospitals do not typically stock commercially available maintenance fluid.

If the animal being treated continues to lose water during the treatment period (e.g., due to continued vomiting, diarrhea, polyuria) this additional amount must be estimated and added to the replacement and maintenance volumes. The volume required to replace continued loss is based on clinical observation (e.g., frequency of defecation, character and volume of feces in the case of diarrhea). Like the volume used to address the initial deficit, the type of fluid selected to replace continuing loss should, in general, resemble the fluid lost. More often than not, balanced electrolyte solutions such as lactated Ringer's are chosen.

Application of the principles outlined above may be appreciated using the following case example. A 2-year-old, 20-kg mixed-breed dog presents with a chief complaint of diarrhea of 2 days' duration. A physical exam reveals a loss of skin elasticity and a definite delay in return of skin to normal position when tented. Both mucous membranes and tongue are dry and the eyeballs feel soft and slightly sunken. Capillary refill time is slightly prolonged. Based on these clinical signs, dehydration is assessed at 8%. The dog is continuing to pass semifluid stools every 2–3 hours, resulting in an estimated ongoing loss of 150 ml/day. The owner reports that the dog is not eating or drinking. Calculation of the volume of fluid to be administered to this dog over the next 24 hours would include

Replacement of initial deficit:	20 kg × 0.08 =	1.6 l
Maintenance needs:	65 ml/kg/day × 20 kg =	1.3 l
Continued loss:		0.15 l
Total estimated fluid needs:		3.05 l

This volume is considered an estimate because it is based on clinical signs and average maintenance losses. Despite the importance of good data collection and appropriate application of fluid therapy principles, at some level adjusting volume is dependent upon a "guess and reassess" process driven by diligent and thorough patient observation (Roussel, 1990).

Rates and Routes of Administration

The rate of fluid and/or electrolyte replacement should parallel the severity of dehydration and electrolyte or acid–base imbalance. Fluids should be administered rapidly at first and then at decreasing rates until the condition is corrected. The rate of infusion is slowed after the first hours of administration to align with a daily administration rate of 200 ml/kg/day or about 8 ml/kg/h. Rates of about 15 ml/kg/h are cited and Cornelius et al. (1978) have shown that rates of 90 ml/kg/h are tolerated in moderately dehydrated, unanesthetized normal dogs. These rates of fluid administration are not recommended for ill animals (e.g., cardiac, renal or other dysfunction) as heart failure can occur with overly aggressive fluid administration. No deaths occurred in the Cornelius study, but clinical signs of severe overhydration were evident in dogs given fluids at 360 ml/kg/h. At 90 ml/kg/h pulmonary artery wedge pressures and central venous pressures were increased in dogs with normally functioning hearts. A seriously ill dog, with compromised cardiac muscle contractility, could be injured by infusion rates that result in acute volume overload. If central venous pressures are being monitored, the infusion rate can be individually adjusted for each patient. This technique is simple and inexpensive. The attending veterinarian should monitor this parameter in the critically ill patient and adjust the rate of fluid administration according to individual needs.

Infusion rates of 50 ml/kg/h have been tolerated in severely dehydrated cases but this is considered aggressive. Less severe cases could be aggressively managed with initial rates of 15–30 ml/kg/h but lower rates are often used. In all cases the rate of infusion should be slowed after the first hour of administration and should be slowed considerably if no urine flow is established. After 4 or more hours of fluid administration without urine flow, the rate of administration should be 2 ml/kg/h or less. Every attempt must be made to establish renal function if no urine flow is detected after 2 hours of fluid administration. To accurately monitor urine flow, all critically ill animals should have a urinary bladder catheter in place.

Common sense and clinical judgment must be exercised. If an animal is severely dehydrated and in shock, it is difficult to administer fluids too fast during the initial stages of treatment. If, however, an animal is almost normally hydrated and the aim is only to maintain hydration, the rate should be slowed considerably. The importance of renal function has been repeatedly emphasized and is typically assessed by measurement of blood urea nitrogen, creatinine, and urine specific gravity.

The route of fluid administration depends on the type of illness being dealt with and the severity of the condition, degree of dehydration, condition of the patient, type of electrolyte imbalance, organic functions of the patient, and time and equipment available. Probably the easiest, most physiological, and most overlooked route of administration of fluid and electrolytes is oral or nasogastric. The oral route is the least dangerous, since the solution can be administered without strict attention to tonicity, volume, and asepsis. Oral replacement of electrolytes by using combinations of electrolyte salts, glycine, and dextrose has been especially successful (Hamm and Hicks, 1975). Proper technique for oral fluid administration should preclude complications associated with fluid aspiration or administration of excessive amounts of air. A relatively unused route of administration that might be considered, especially in very young animals, is per rectum. Warm water, K^+, Na^+, and Cl^- are well absorbed via this route. It may be difficult, however, to get the animal to retain material given in this manner, especially in the presence of gastrointestinal disease. Rectal infusion of fluids in birds has been suggested as an effective alternative route to intravenous, intraosseous, oral, or subcutaneous (Ephrati and Lemeij, 1997).

The most commonly used and perhaps most practical routes of fluid and electrolyte administration are the parenteral routes: intravenous (IV), subcutaneous (SC), intraperitoneal (IP), or intraosseous (IO). The IV route is the most versatile. Severe disturbances of fluid and electrolyte balance demand it. Nearly all the toxicity of solutions administered in this manner is more related to rate than volume or composition. No indications for hypotonic solutions have been found, but indications for isotonic and hypertonic solutions exist, and some of these have been discussed previously. Some of the problems associated with IV administration include those associated with maintenance and asepsis of indwelling catheters, clotting, and hematomas, as well as the location of a vein on very small or very ill animals. Obviously, the fluids administered and equipment used must be sterile. Large volumes of fluid administered too rapidly may overload the circulatory system, causing pulmonary edema and even death, especially in severely ill or toxic cases. This is the preferred route for blood, blood plasma, and plasma volume expanders.

Subcutaneous administration of fluid is referred to as hypodermoclysis. This technique is convenient for correction of mild to moderate deficits in small animals. Fluids are absorbed more slowly than by the IV route, but if the animal is not in critical condition, this is of no real consequence. Only isotonic solutions should be used in this manner. Dextrose of any tonicity or any solutions lacking electrolytes in isotonic levels are contraindicated because they may produce an initial rapid diffusion of major extracellular electrolytes to the area. This can result in severe reactions, including death, especially if the animal is already in shock. Hypodermoclysis is extremely valuable in very young or very small animals. If the animal is difficult to restrain long enough for a prolonged IV infusion, this is a useful technique. When edema is present, absorption will not occur, and this route of administration is contraindicated. If the animal is chilled by a cold environment or a cold fluid is injected, absorption by this route will be delayed, and it is recommended that fluids be prewarmed to body temperature when feasible. Administration of fluids in one anatomical location should be limited to amounts that are readily absorbed (approximately 10–12 ml/kg) (Greco, 1998). Fluid should be deposited dorsally along the area bordered by the scapulae anteriorly and the iliac crests posteriorly. Hypodermoclysis is not commonly used as a route of administration in large animals.

IP infusion of fluids has the same restrictions as those for hypodermoclysis. The technique may predispose to peritonitis, so aseptic procedures must be used. The fluids are mobilized faster than in SC administration, but this route is potentially more hazardous (puncture of abdominal organs). Nevertheless, this is a good route for electrolyte and water absorption. Plasma and a large percentage of red blood cells administered using this technique are rapidly absorbed. In large animals it can be a very practical method of treatment, since a large quantity of fluid can be administered rapidly with few adverse effects. Perhaps the greatest application of this technique is with peritoneal lavage.

Intraosseous fluids are administered through a catheter placed into bone. This route may be chosen if vascular access is limited or cannot be performed in adequate time due to very small patient size, cardiac arrest,

Table 23.18 Indications, dosages, administration, and side effects associated with use of selected colloids in dogs. Source: Modified from Rudloff and Kirby, 1998. Other sources for information in table include Mathews, 1998 and Hughes, 2000.

Type of colloid	Indications	Dosage and administration	Side effects and contraindications
Plasma	Coagulopathies; disseminated intravascular coagulation; low antithrombin; acute hypoalbuminemia.	20–30 ml/kg/day administered: (a) continuously over 24 h, (b) as a 2–4 h infusion, (c) 6–10 ml/kg in 1-h infusions every 8 h, or (d) until plasma albumin is over 2.0 g/dl. Approximately 22.5 ml/kg of plasma needed to increase patient albumin by 5 g/l.	Rapid volume expansion may be detrimental to patients with oliguric or anuric renal failure or congestive heart failure.
Dextran 40	Rapid, short-term intravascular volume resuscitation from hypovolemic shock; rapid improvement of microcirculatory flow by lowering blood viscosity; prophylaxis of deep vein thrombosis and pulmonary emboli.	10–20 ml/kg/day IV bolus to effect; with distributive shock due to SIRS dextran can be followed by a CRI of hetastarch to maintain MAP of at least 80 mm Hg.	*See* plasma. Dilutional effect on serum coagulation factors in addition to possible direct effects on these factors. Contraindicated in patients with severe coagulopathies. Sludging of RBCs in microcirculation in dehydrated patients may occur if sufficient crystalloids are not administered. Anaphylaxis reported in humans. AKI has been reported.
Dextran 70	Rapid, intravascular volume resuscitation from hypovolemic, traumatic, or hemorrhagic shock.	*See* dextran 40.	*See* dextran 40. Dextran 70 is thought to impair coagulation more than dextran 40. No AKI reported.
Hetastarch (hydroxyethyl starch or HES)	Rapid, intravascular volume resuscitation from all forms of shock; small-volume resuscitation; volume replacement and maintenance in SIRS patients.	10–40 ml/kg/day IV bolus to effect; with cardiogenic shock, pulmonary contusions, or head injury, 5 ml/kg boluses are administered to effect, using the smallest volume possible to maintain MAP of 80 mm Hg.	*See* dextran 40. Anaphylaxis has not been reported with hetastarch, but pruritus possibly associated with deposits of HES in cutaneous nerves has been reported in up to 33% of patients treated with long-term infusions. AKI may be a concern.
Pentastarch (PEN)	Rapid, intravascular volume resuscitation from hypovolemic, traumatic, or hemorrhagic shock.	10–25 ml/kg/day; terminal half-life shorter than HES.	*See* dextran 40. Anaphylaxis and AKI have not been reported.
Vetstarch	Treatment and prophylaxis of hypovolemia. Not a substitute for red blood cells or coagulation factors in plasma	Up to 20 ml/kg/day in small animal patients; infuse initial 10–20 ml slowly and observe for possible anaphylactoid reactions.	See dextran 40.

AKI, acute kidney injury; CRI, constant-rate infusion; MAP, mean arterial pressure; SIRS, systemic inflammatory response syndrome.

hypovolemic shock, or patient anatomy (Mazzaferro, 2009).

Products for Fluid Therapy

Major categories of parenteral fluids include crystalloids, colloids, blood replacements, and nutritional solutions. Blood replacement products (whole blood, blood components, and red blood cell substitutes) and nutritional solutions (amino acids and fat emulsions) are considered elsewhere. The composition and characteristics of selected crystalloid solutions and additives used to spike parenteral solutions are listed in Table 23.17. Types and recommended dosages of synthetic colloids are listed in Table 23.18.

Crystalloids

As detailed in Table 23.17, crystalloid solutions are polyionic but differ in the amount of each ion and in tonicity. As discussed previously, the tonicity of parenteral fluids partially dictates distribution of volume into interstitial and intracellular spaces. Fluids that most closely resemble the ECF are isotonic, high in sodium, and low in potassium and may be acidifying or alkalinizing. These replacement fluids, also referred to as balanced electrolyte solutions (BES), may be given in large volumes at a rapid rate to patients in shock in an attempt to reestablish effective perfusion without severely altering electrolyte concentrations. Alkalinizing solutions depend upon metabolism of various substrates (e.g., lactate, acetate, gluconate) to alkalinizing equivalents in order to reduce acidemia. Lactate and acetate are metabolized in the liver and muscle, respectively, while gluconate is metabolized widely in the body. Perfusion and function of the liver are required for generation of alkalinizing equivalents from the most commonly used replacement fluid, lactated Ringer's solution. A large percentage of veterinary patients that require fluid therapy suffer from nonrespiratory acidosis and are treated with alkalinizing balanced electrolyte solutions. These fluids are generally indicated for animals suffering from diarrhea, vomiting (assuming vomitus contains bile), renal disease, trauma, and shock and those requiring pre- and postsurgical support. To avoid calcium precipitation, calcium-containing balanced electrolyte solutions, such as lactated Ringer's solution, should not be coadministered through the same port with whole blood or sodium bicarbonate.

Normal saline and Ringer's solution are considered acidifying solutions and are used to treat the relatively small percentage of small-animal patients that present with metabolic alkalosis. Both solutions are high in chloride and promote renal excretion of bicarbonate. Normal saline is also commonly used in treatment of patients with electrolyte disorders such as hyperkalemia or hypercalcemia in which absence of electrolytes in parenteral fluids is desirable. Assuming appropriate insulin therapy is instituted, normal saline is also considered the fluid of choice for treatment of diabetic ketoacidosis.

Colloids

The critical distribution of water between plasma and interstitial fluid is maintained in part by the colloid osmotic pressure (COP) of plasma protein. COP includes the osmotic pressure exerted by plasma proteins and their associated electrolyte molecules. This force draws water into capillaries and balances the hydrostatic pressure driving water out (see Starling relationships described in Section Fluid and Electrolyte Distribution). Although the basic concept of Starling relationships is straightforward, in vivo application of these concepts is complicated by the heterogeneity of Starling forces within different tissues and the complexity of transvascular fluid dynamics. Despite these caveats, it is practical to say that the balance between intravascular COP and capillary hydrostatic pressure drives net fluid extravasation and forms the basis for intravenous colloid therapy.

Therapeutic colloids may be of two types: natural and synthetic. Natural colloids include whole blood, plasma, and albumin. Synthetic colloids, include dextran 40, dextran 70, hetastarch, pentastarch, and oxypolygelatin. Therapeutic colloid solutions contain large particles and are retained within the vascular space more readily than crystalloids. As a result, smaller volumes of colloids cause greater volume expansion than crystalloids do. Initial tissue perfusion has been found to be better after volume expansion with colloids or combinations of colloids and crystalloids than with crystalloids alone (Funk and Baldinger, 1995). The duration of this effect varies and is dependent upon many variables, including the species of animal, dose, specific colloid formulation, preinfusion intravascular volume status, and microvascular permeability (Hughes, 2000).

The osmotic effect of colloid solutions is related to the number of particles rather than the size of particles in a solution. However, heterogeneity of particle size causes considerable complexity in the pharmacokinetics of these solutions. Synthetic colloids contain molecules that vary in molecular weight more than the molecules in a solution of a natural colloid such as albumin. After synthetic colloids are administered, the smaller molecules pass rapidly into the urine and are eliminated or move to the interstitium, negating their ability to attract water into the vasculature. Larger molecules remain in the circulation to exert COP until they are hydrolyzed by amylase or removed by the monocyte phagocytic system. Because of differences in particle behavior and in pharmacokinetic study design (e.g., duration of study, volume status of study subjects, volumes and rates of colloid administration), specific half-lives reported for colloids may vary considerably (Mathews, 1998). Such variation may pose therapeutic problems since actual duration of action of colloids may not coincide with manufacturer estimates of the same.

Indications for colloid use include perfusion deficits, hypooncotic states, deficiency of blood components, and diseases that lead to systemic inflammatory response syndrome (SIRS). SIRS is a generalized inflammatory process with evidence of decreased organ perfusion. Sepsis may be the source of SIRS but other conditions may also result in generalized systemic pathophysiology (e.g., heat stroke, acute pancreatitis, and neoplasia). Hallmarks of SIRS include alterations in temperature, heart rate, respiratory rate, $P\text{CO}_2$, and white blood cell count. Peripheral vasculature dilates, capillary permeability increases, and plasma proteins leak from affected vessels. The resulting hypoalbuminemia leads to a reduction in COP, loss of vascular volume, and hypoperfusion of tissues. High-molecular-weight colloids administered to SIRS patients are retained more effectively in leaky vessels and force retention of volume. Approximately 20–24% of crystalloid remains within the vasculature 1 hour after infusion into normal animals compared with 100% of the volume of infused colloid. Hence, colloids may initially expand the volume of the intravascular space approximately fourfold more than crystalloids (Hughes, 2000).

Colloids are often included in fluid regimens for small-volume resuscitation (e.g., during traumatic, hypovolemic, or cardiogenic shock), improvement of microcirculatory flow and capillary integrity (e.g., SIRS), and management of ongoing hemorrhage. While colloids are useful in reestablishing vascular integrity, replenishment of interstitial and intracellular fluid deficits depends upon appropriate use of colloids and crystalloids in combination. Colloid administration typically reduces the required amount of crystalloid fluid by as much as 40–60% (Rudloff and Kirby, 1998). Care must be taken to adjust amounts and rates of all fluids administered to prevent intravascular volume overload and subsequent interstitial edema. Monitoring of colloid therapy ideally includes direct measurement of COP with a membrane osmometer in addition to measurement of traditional indices of perfusion and hydration.

Problems associated with colloid therapy may include dilutional effects caused by expansion of the intravascular space. Packed-cell volume, albumin concentration, serum potassium concentration, and amount of circulating coagulation factors typically decline following administration of synthetic colloids. Rapid volume expansion may be of greatest concern in patients with oliguric or anuric renal failure or congestive heart failure. Precipitation of acute renal failure (now more commonly referred to as acute kidney injury) has been reported in humans with dextran 40 (Ferraboli et al., 1997) and is also of concern in veterinary patients (Hayes et al., 2016). Impairment of coagulation as a result of dilution of coagulation factors is another clinically important potential side effect (Gauthier et al., 2015). Adverse effects and lack of outcomes advantages of resuscitation using colloids as compared to crystalloid solutions has been shown in humans and is of concern in veterinary patients (Cazzolli and Prittie, 2015). Anaphylactic or anaphylactoid reactions associated with colloids have been reported in humans. Concern has also been raised over the effects of selected colloids on reticuloendothelial function (Hughes, 2000). Because cats are more likely to show signs of allergic reactions, especially when synthetic colloids are administered quickly, only small volumes infused at slow rates (5 ml/kg increments given over 5–10 minutes, repeated to effect up to 20 ml/kg) are recommended for use in this species.

Table 23.18 lists indications, dosages, and administration details for colloids used to treat dogs. Albumin (66,000–69,000 daltons) accounts for 80% of the COP of the only natural colloid listed, plasma. Each gram of albumin can retain as much as 18 ml of fluid in the intravascular space, assuming infused albumin does not leak from damaged vessels. The intravascular half-life of albumin in plasma is approximately 16 hours (Mathews, 1998). The three major categories of synthetic colloids are dextrans, hydroxyethyl starches, and gelatins. Dextrans are prepared from a macromolecular polysaccharide produced by bacterial fermentation of sucrose. Because these products represent a range of molecules with different molecular weights, they are described by a weight average molecular weight (MWw). MWw is defined as the sum of the number of molecules at each molecular weight times their mass divided by the total weight of the molecules. Dextran 70 (MWw = 70,000 daltons) was used in the past as a 6% solution in either 0.9% saline or 5.0% dextrose but is no longer readily available. Hydroxyethyl starches are derived from plant amylopectin and are modified by hydroxyethylation to reduce hydrolysis by amylase. Hetastarch (Hespan®) has a MWw of 100,000–300,000 daltons and is available as a 6% (6 g/dl) solution in 0.9% saline. Vetstarch (Voluven®)(6% hydroxyethyl starch 130/0.4 in 0.9% sodium chloride) is increasingly preferred due to fewer side effects. Pentastarch has a narrower range of molecular weights and a shorter duration of action than hetastarch. In the United States pentastarch is only approved for leukapheresis, while in Canada it is approved as a plasma volume expander. In 2013, the FDA announced a boxed warning on increased mortality, renal injury, and risk of bleeding with use of hydroxyethyl starch solutions in some settings with human patients.

Hypertonic Solutions

For several decades, resuscitation of experimental and clinical animals suffering from shock has been attempted using hypertonic saline (HSS), and studies have generally supported the benefits of HSS for transient restoration of cardiovascular function. Although a full understanding of the mechanism of action has been elusive, there is agreement that the primary benefits of HSS infusion result from plasma volume expansion. High circulating concentrations of sodium attract water into the vasculature from the interstitial and intracellular spaces and help to restore capillary flow and tissue perfusion. Cardiac output has been reported to increase as a result of increased preload, decreased afterload related to systemic and pulmonary vasodilation (Constable et al., 1995), increased adrenergic activity through release of catecholamines, and improved oxygen delivery to the heart (Tobias et al., 1993). Positive inotropy has also been reported but this remains a controversial point (Cambier et al., 1997). In vitro studies have shown that, at least during the initial treatment period, negative inotropy may predominate (Constable et al., 1994). All of the above effects are short lived (peak occurs within approximately 1 hour) but resuscitative benefits may be prolonged by combination of HSS with colloids such as dextran 70. Ideally, rapid recovery of cardiovascular parameters occurs with administration of smaller volumes of HSS or HSS plus dextran (HSD) compared to crystalloids, thus decreasing the risk of edema related to volume overload. In addition to primary volume expansion, HSS is thought to invoke a lung vagal reflex important to circulatory control during hypovolemia. How much this reflex contributes to the cardiovascular effects of HSS infusion remains controversial. HSS may also have immunomodulatory effects that protect organs from oxidative injury and enhance cell-mediated immunity (Coimbra et al., 1996).

HSS use is indicated in the treatment of shock associated with hemorrhage (Bauer et al., 1993), trauma (Schertel et al., 1996), gastric-dilatation volvulus (Schertel et al., 1997), acute pancreatitis (Horton et al., 1989), burns (Horton et al., 1990), and sepsis (Fantoni et al., 1999; Maciel et al., 1998). The evidence for use of HSS in the first three of these is most compelling, with fewer studies unequivocally demonstrating advantage under specific study conditions associated with the other disorders. HSS has also been utilized in treatment of head injury since, like mannitol, HSS draws interstitial and intracellular water away from edematous tissues and into the vasculature (Prough and Zornow, 1998). Regardless of the indication, HSS effects are transient, necessitating combination with crystalloids or colloids to achieve long-term resuscitative goals. Effects of HSS should be monitored by improvement in cardiovascular parameters correlated with increased perfusion as well as by assessment of mean arterial blood pressure, electrocardiogram, and electrolytes. Monitoring is aimed at preventing volume overload and electrolyte imbalances that may occur as a result of therapy.

HSS use is contraindicated in hypernatremic patients or those with increased plasma osmolality. Use in dehydrated animals is controversial since these patients frequently suffer from increases in both parameters. Studies that support HSS use in the presence of dehydration include those in which resuscitation with HSD of hypovolemic, diarrheic calves found this method to be at least as effective as others (Constable et al., 1996; Walker et al., 1998). In animals suffering from shock related to trauma and hemorrhage, two additional problems, hypokalemia and increased risk of rehemorrhaging, may be of concern. Rehemorrhage – bleeding caused by breakdown of clots in areas where hemorrhage has previously occurred – may be related to the sudden increase in cardiac output and arterial blood pressure associated with HSS resuscitation (Schertel and Tobias, 2000). HSS may also dilute circulating coagulation factors and affect platelet function. As with colloids, these concerns may only be of practical significance if the patient suffers from preexisting coagulopathies or thrombocytopenia. Using a swine model of hemorrhagic shock, Dubick et al. (1993) demonstrated that the combination of 7.5% NaCl/6% dextran 70 did not significantly affect various measures of coagulation and platelet aggregation in their model. Studies continue to address the pros and cons of HSS use in various animal models and in clinical patients (Krausz, 1995). Variation across species lines, differences in physiological circumstances of each study, and different views of cost versus benefit ratios may account for differing conclusions on the overall value of HSS treatment.

HSS is administered most effectively in combination with colloids or crystalloids in order to optimize resuscitative effects; 5% HSS, at a dose of 6–10 ml/kg, and 7–7.5% HSS, at a dose of 4–8 ml/kg, are administered at a rate of 1 ml/kg/min. Similar dosages may be used for HSD. More rapid administration rates may invoke a vagal-mediated hypotension, decreased heart rate, bronchoconstriction, and rapid, shallow breathing. To prepare 7% saline in 6% dextran 70, 33.0 g of anhydrous sodium chloride is added to a 500 ml bag of 6% dextran 70 in 0.9% saline. Half of the sodium chloride crystals are placed into the barrel of a 35 ml syringe and an adequate volume of dextran 70 solution is drawn into the syringe to dissolve the crystals. This solution is filtered through a 0.22 μm filter and is injected back into the bag of dextran 70. The procedure is repeated a second time to dissolve the remaining half of the sodium chloride (Schertel and Tobias, 2000). Although a reported advantage of HSS is presumed sterility due to hypertonicity, St. Jean et al. (1997) have demonstrated the ability of bacteria to adapt and survive in the hypertonic environment of HSS. Hence, aseptic technique consistent with handling of all intravenous fluids should be followed.

Blood Substitutes

The term *oxygen carrier* (or *oxygen therapeutic*) has replaced the terms *blood substitute* and *red blood cell substitute* because it more appropriately describes the common oxygen-carrying role of these agents, which have some but not all of the functions of blood (Wohl and Cotter, 1995; Awasthi, 2005). Two types of products have been developed for use as oxygen carriers—perfluorocarbons (PFCs) and hemoglobin-based oxygen carriers (HBOCs). Neither of these two types of products are currently readily available.

Perfluorochemicals

Perfluorochemicals are comprised of carbon and fluoride, are chemically inert, and are insoluble in water.

They were originally developed as hydraulic fluids and transformer coolants but are used as oxygen carriers because of their ability to dissolve oxygen and carbon dioxide. PFCs have a high oxygen solubility and are emulsified with a surfactant for intravenous administration. Unemulsified PFCs can dissolve 40–56 ml of oxygen per 100 ml of liquid while emulsified PFC dissolves 5–8 ml O_2/100 ml. The oxygen content of PFC has a linear dependence on $P\text{O}_2$ and in order to transport physiological quantities of oxygen a very high oxygen tension is needed. This factor limits the use of PFCs as oxygen carriers to situations where high oxygen tension can be maintained (e.g., surgery). PFCs have a short intravascular half-life, can activate the complement cascade, and have a slow elimination (Rentko, 1992; Wohl and Cotter, 1995).

Fluosal-DA is a 20% (by weight) emulsion previously licensed by the FDA for use in humans during coronary angioplasty surgery. PFC can also be potentially used during tumor radiation therapy, vascular surgery, extracorporeal organ perfusion, peritoneal lavage, and carbon monoxide poisoning (Rentko, 1992; Wohl and Cotter, 1995).

The half-life of perfluorochemicals depends upon the molecular size and structure of the agent. PFCs are expired in the lungs after phagocytosis by fixed macrophages, primarily in the liver and spleen (Wohl and Cotter, 1995).

Hemoglobin-Based Oxygen Carriers

Hemoglobin-based oxygen carriers (HBOCs) are useful for replacing red blood cells in anemic humans and animals. These products contain purified hemoglobin, removed from red blood cells and suspended in solution, and are especially useful when compatible red blood cells are not available. These solutions can pass through microcirculation more readily than red blood cells making them ideal for treating severe anemia or hypovolemia due to acute hemorrhage or poor blood flow distribution (Callan and Rentko, 2003; Lichtenberger, 2004).

HBOCs are developed from animal or human hemoglobin. Hemoglobin is an iron-containing protein composed of a tetramer of two α-chains and two β-chains with a heme molecule within the folds of each chain. When hemoglobin is administered, it breaks down into its constituent chains and has toxic effects (Awasthi, 2005). The dissociation is also associated with a short circulation half-life (Rentko, 1992). Small-sized, modified hemoglobin chains tend to extravasate, sequester nitric oxide, and cause vasoconstriction (Awasthi, 2005).

Cross-linking, glutaraldehyde polymerization, or polyethylene glycolation of hemoglobin prevents dissociation, improves the circulation half-life, and increases the size of the molecule to reduce extravasation (Rentko, 1992; Awasthi, 2005). The amount of cross-linking, polymerization, or polymer-linking also affects the viscosity of HBOC solutions. HBOCs cause an increase in plasma hemoglobin concentration and act as colloids to cause volume expansion (Wohl and Cotter, 1995; Awasthi, 2005).

Encapsulation is another technique used to stabilize hemoglobin. Hemoglobin can be encapsulated in nonantigenic phospholipids (liposomes), which prevents glomerular filtration and increases the half-life compared to free hemoglobin. Initial problems associated with encapsulated hemoglobin are related to reticuloendothelial stimulation, contamination with endotoxins, and rapid clearance (Rentko, 1992; Awasthi, 2005).

The only commercially available HBOC approved by the FDA for use in veterinary species is Oxyglobin® (OPK Biotech LLC, Cambridge, MA). Oxyglobin (hemoglobin glutamer-200 [bovine]), approved for use in the United States for treatment of anemia in dogs, is given as a single dose (10–30 ml/kg, 1.3–3.9 g/kg) administered at a rate no greater than 10 ml/kg/h (Hamilton et al., 2001; Callan and Rentko, 2003). This product is a purified and chemically modified bovine hemoglobin, which is stable at room temperature, has a shelf-life of 3 years, and has a similar oxygen-carrying capacity as endogenous hemoglobin (Senior, 1998; Callan and Rentko, 2003; Awasthi, 2005). The hemoglobin is polymerized to glutaraldehyde and is reconstituted in a modified lactated Ringer's solution (Hamilton et al., 2001; Lichtenberger, 2004). Oxyglobin does not need to be cross-matched and does not have the potential to transmit disease (Lichtenberger, 2004); therefore, it may be useful in emergencies when there is not time to cross-match or prepare blood products (Lanevschi and Wardrop, 2001).

The product has an osmolality of 300 mOsm/kg, lower viscosity than whole blood, hemoglobin concentration of 13 g/dl, colloidal oncotic pressure of 20–25 mm Hg, and a half-life of around 36 hours (30–40 hours) (Rentko, 1992; Senior, 1998; Callan and Rentko, 2003; Lichtenberger, 2004). It has a pH of 7.8 and expands the intravascular space by at least its own volume (Lichtenberger, 2004). Oxyglobin is not associated with renal toxicity, and there is no clinical evidence of allergic reaction with repeated doses (Rentko, 1992). Hamilton et al. (2001) demonstrated that multiple administrations of Oxyglobin (nine administrations over 50 weeks) in eight splenectomized dogs produced neither adverse physiological effects nor adverse pathological effects. Although most dogs produced Oxyglobin-specific IgG antibodies, no anaphylactic or anaphylactoid reactions were noted and the development of IgG antibodies did not affect the oxygen-carrying capacity (Senior, 1998; Hamilton et al., 2001).

The oxygen affinity of Oxyglobin is dependent on chloride ion concentration rather than the concentration of 2,3-diphosphoglycerate (2,3-DPG) (Lichtenberger, 2004). In humans and dogs the oxygen affinity of hemoglobin is determined by the interaction of hemoglobin and 2,3-DPG in red blood cells (Rentko, 1992). The levels of 2,3-DPG decrease in blood stored over 1 week, which leads to increased oxygen binding and decreased delivery of oxygen to the tissues. Compared to canine blood, Oxyglobin has a lower oxygen affinity enhancing oxygen delivery to tissues (Lichtenberger, 2004). One gram of hemoglobin from Oxyglobin can deliver the same amount of oxygen to tissues as 3–4 grams of red blood cell hemoglobin (Callan and Rentko, 2003).

Twenty-four hours after being opened, the product must be discarded due to the production of methemoglobin and to avoid bacterial contamination (Callan and Rentko, 2003; Lichtenberger, 2004). Oxyglobin is stored in its deoxygenated state and becomes oxygenated when it passes through the lungs (Senior, 1998). The primary effects of Oxyglobin last about 24 hours, and 90–95% percent of Oxyglobin is eliminated in 5–9 days (Senior, 1998; Callan and Rentko, 2003; Lichtenberger, 2004).

The volume of distribution, plasma clearance, and terminal elimination half-life of Oxyglobin are dose dependent, and administration of this product increases plasma hemoglobin concentrations. Medications should not be added to the bag, and fluids and drugs should not be administered through the same infusion set as Oxyglobin (Callan and Rentko, 2003).

Hemopure® (hemoglobin glutamer-250 [bovine]) (OPK Biotech LLC, Cambridge, MA) is a glutaraldehyde-polymerized bovine hemoglobin similar to Oxyglobin approved in South Africa for use in humans (Callan and Rentko, 2003; Awasthi, 2005). Hemopure can transport oxygen, needs no refrigeration, is compatible with all blood types, has a long shelf life, and has a minimized risk of disease transmission (Fitzpatrick et al., 2005). Fitzpatrick et al. (2005) demonstrated in laboratory studies that Hemopure reversed anaerobic metabolism in the treatment of hemorrhagic shock without end-organ damage. The decreased urine output noted in animals given Hemopure in laboratory studies has been attributed to the smaller volumes needed to resuscitate the animals and has not been associated with long-term decreased renal function (Fitzpatrick et al., 2005). Animal studies with Hemopure have demonstrated that it can carry oxygen more efficiently than red blood cells on a per-gram basis (Hamilton et al., 2001).

PolyHeme® (Northfield Laboratories, Evanston, IL) is a glutaraldehyde-polymerized human hemoglobin-based product (Awasthi, 2005).

Hemospan® (MP4 or MPEG-Hb) (Sangart, San Diego, CA) is a polyethylene glycolated hemoglobin (Awasthi, 2005; Björkholm et al., 2005). MP4 is very viscous, made from stroma-free human hemoglobin, has a high oxygen affinity, and is reported to not cause vasoconstriction (Awasthi, 2005; Björkholm et al., 2005). Based on in vitro and animal studies, the lack of vasoconstriction (i.e., avoidance of engaging autoregulatory vasoconstriction) is thought to be related to increased molecular size and oxygen affinity, which lead to a decreased diffusive oxygen transfer in the plasma space (Björkholm et al., 2005).

Cross-linking or polymerization stabilizes the structure of HBOCs so that there is almost no urinary excretion. Some modified hemoglobin may still be deposited in renal tubules. Other sites of deposition for HBOCs are lymph, liver, and spleen. HBOCs use fixed macrophages in their metabolism, which may impair macrophage phagocytic ability (Wohl and Cotter, 1995).

Adverse Effects

One of the shortcomings of early HBOCs was nephrotoxicity associated with contamination with red blood cell stromal elements. Current HBOCs are ultrapurified to prevent contamination (Callan and Rentko, 2003).

HBOCs should be used cautiously in euvolemic or hypervolemic patients to avoid volume overload related to the colloidal effects of HBOCs. Cats and small mammals appear to be more predisposed to pulmonary edema following volume overload (Lichtenberger, 2004). Circulatory overload is dependent on rate of infusion and is most marked in dogs receiving greater than 10 ml/kg/h and cats receiving more than 5 ml/kg/h (Wohl and Cotter, 1995; Callan and Rentko, 2003). Because HBOCs are colloids, they should be used cautiously in patients with preexisting cardiopulmonary disease (Callan and Rentko, 2003).

Ischemia–reperfusion injury is common to all HBOCs and occurs due to production of free radicals by hemoglobin and its oxidation products (Awasthi, 2005). HBOCs can provide oxygen and iron as electron donors leading to oxygen radical production and tissue damage (Wohl and Cotter, 1995).

Anaphylactic reactions are a possibility (though not documented in clinical or research cases) with repeated administration of heterologous HBOCs (Wohl and Cotter, 1995; Callan and Rentko, 2003; Awasthi, 2005). If hypersensitivity occurs, infusion of the HBOC should be discontinued, and appropriate resuscitation measures should be implemented (e.g., crystalloids, epinephrine).

Adverse effects of HBOCs in dogs, cats, and small mammals are discoloration of mucous membranes, sclera, and urine (Wohl and Cotter, 1995; Callan and Rentko, 2003; Lichtenberger, 2004). In bird species no discoloration of urine or mucous membranes is noted. Measurements of colorimetric lab tests are affected for 24–72 hours after Oxyglobin administration (Lichtenberger, 2004).

Hypertension can also be an adverse effect of hemoglobin solutions. HBOCs have a pressor effect that is attributed to sequestration, or scavenging, of nitric oxide following extravasation, but other mechanisms may be involved including endothelin release and sensitization of peripheral α-adrenergic receptors (Callan and Rentko, 2003; Fitzpatrick et al., 2005). Polymerization or polyethylene glycolation of hemoglobin decreases extravasation but does not completely eliminate its pressor effect (Awasthi, 2005; Fitzpatrick et al., 2005).

It is beyond the scope of this chapter to compare treatments for hemorrhagic shock, but much has been written on the topic, including therapy with blood substitutes. In a study comparing autologous/shed blood, hemoglobin-based oxygen carrier/Oxyglobin, crystalloid/saline, colloid/Hespan (6% hetastarch), and vasopressin in a canine hemorrhagic shock model (50–55% total blood loss with a mean arterial pressure of 45–50 mmHg as a clinical criterion), all resuscitation modalities except vasopressin restored microvascular and systemic function changes close to prehemorrhagic values. Autologous blood was the only treatment that restored oxygenation changes to prehemorrhagic levels (Cheung et al., 2007).

Special Topics

Horses

Horses present some special problems in acid–base management. In cases of severe diarrhea, shock, and intestinal obstruction, the horse seems predisposed to severe metabolic acidosis (Waterman, 1977). Electrolyte disorders common in horses with acute abdominal disease have been reviewed (Borer and Corley, 2006a,b). Respiratory acidosis is a very common sequel to closed-circuit inhalation anesthesia in the horse. An abnormally low concentration of Na^+ is a common problem in dehydrated horses. Severe hypokalemia, with blood K^+ values less than 2.5–3 mEq/l, may require treatment with solutions high in K^+. Dangerous hyperkalemia, with blood levels greater than approximately 7 mEq/l, may be associated with acidosis in foals. Prompt correction of the acidosis will usually correct the hyperkalemia.

Cattle

Ruminants also present special fluid and electrolyte management problems. When a diagnosis of abomasal disease is coupled with an obvious fluid balance disorder, hypochloremia, hypokalemia, and alkalosis are usually present. These should be confirmed by appropriate laboratory tests. Grain overloading will result in severe dehydration and metabolic acidosis. Calf diarrhea also results in severe dehydration and metabolic acidosis, with dangerous hyperkalemia in some cases. If hyperkalemia exists, one must guard against administration of even more K^+. When dealing with herbivores, it is important to remember that normal feed contains high levels of K^+. When these animals are anorexic, they frequently become K^+ depleted. The best way to replace K^+ deficits is by consumption of hay or grass, but K^+ must be added parenterally when the situation dictates. A wide variety of electrolyte mixtures containing K^+ are available for oral administration.

Intravenous administration of 5% dextrose alone or with isotonic sodium bicarbonate to hypernatremic, diarrheic calves has been preliminarily observed to provide benefit (Abutarbush and Petrie, 2007). Despite the fact that the average reduction rate of serum sodium concentration in these calves ($n = 5$) was about four times that recommended, no complications were reported in this small cohort. Further studies are needed to determine how this approach compares with other therapies.

Anesthetic and Surgical Effects

General anesthesia may exert several effects on water, electrolyte, and acid–base balance. Almost all general anesthetics induce some degree of Ca^{++} channel blockade, resulting in some degree of vasodilation and myocardial depression. The end effect can be a reduction in cardiac output and/or alterations in organ blood flow. Arterial pressures are frequently lowered in a dose-dependent manner, and GFR may be affected. The commonly used inhalation anesthetic agents (halothane, enflurane, and isoflurane) all cause direct systemic vasodilation. Narcotics and some muscle relaxants also can cause vasodilation. As a result of the vasodilation, fluid requirements may be increased during the course of the surgical procedure to maintain adequate blood pressure and cardiac output. After recovery from the general anesthetic, when vascular tone is normalized, the patient may be volume overloaded and hypertensive. Fluid loss may also increase during general anesthesia as a result of tracheal intubation and/or artificial ventilation. Normal mechanisms for the humidification of inspired air are bypassed, and the cold, dry gases from the anesthesia machine can cause a considerable amount of fluid loss. Open body cavities allow for evaporative losses. Third spacing may occur with extravasation of fluid from the vascular to the extravascular, extracellular spaces. If extravasated fluid is replaced to maintain adequate circulatory volumes, the patient with inadequate cardiac reserve or poor renal function may suffer fluid overload and congestive heart failure when postoperative redistribution of the fluid back into the circulation occurs (Gold, 1992).

Surgical injury can result in significant reductions in serum albumin, total proteins, and total lymphocyte counts. These decreases are typically greater following abdominal surgery. The decreases have been found to be primarily caused by the volume of IV fluids frequently required for resuscitation and to compensate for blood loss.

Acknowledgment

Dr. Claire Fellman, Department of Clinical Sciences, Cummings School of Veterinary Medicine, Tufts University provided expert peer review of this chapter.

Diuretics and Renal Pharmacology

Butch Kukanich and Deborah T. Kochevar

This chapter presents the physiological basis for fluid and electrolyte balance, including discussion of selected renal mechanisms for regulation of water, sodium, chloride, potassium, hydrogen, and bicarbonate. In this chapter these concepts will be extended in order to understand the mechanism of action, therapeutic uses, and side effects of diuretic agents and renal pharmacology. Diuretic agents are used to mobilize tissue fluid, most often in the treatment of edema of cardiac, renal, or hepatic origin. The history of diuretics dates back to consumption by Paleolithic humans of caffeine-containing plants. Besides xanthine derivatives such as caffeine, osmotic diuretics were clinically important prior to the 20th century. The use of mercurial diuretics, now therapeutically obsolete, began in the early 1900s and was followed by introduction of the first modern diuretic, acetazolamide, in the mid-1950s. By the late 1950s and early 1960s the formulary of modern diuretics included chlorothiazide, furosemide, and potassium-sparing diuretics (Morrison, 1997). These drugs and their relatives constitute the mainstays of diuretic treatment. Finally, the renin–angiotensin–aldosterone system will be discussed, which can be activated by different mechanisms resulting in local and systemic effects including vascular and renal effects.

Renal Physiology

Nephron Function

Knowledge of renal anatomy and physiology is essential to understanding the mechanism of action of diuretic drugs. Although a thorough review of these topics is beyond the scope of this text, a brief overview of nephron function is provided. The basic functional unit of the kidney is the nephron, which consists of a filtering apparatus, the glomerulus, connected to an extended tubular structure that reabsorbs and conditions the glomerular ultrafiltrate to produce urine. Each kidney is composed of thousands of nephron units. Figures 24.1 and 24.2 are drawings of single nephron units, indicating the broad subdivisions of nephron segments and the sites of action of diuretic agents. This diagram provides the simplest nomenclature for nephron segments. As knowledge of the function and epithelial morphology of each segment has increased, the tubular portion of the nephron has been subdivided into approximately 14 shorter segments referred to by a standardized nomenclature (Kriz and Kaissling, 1992).

Blood flow through the kidney goes from the renal artery into smaller arteries until it reaches the afferent arteriole (Figure 24.1). The afferent arteriole becomes the glomerular capillaries (where glomerular filtration occurs) then the efferent arterioles. The efferent arterioles carry blood into the peritubular capillaries, which surround the renal tubules and is where the majority of the glomerular filtrate (water, electrolytes, glucose, etc.) is reabsorbed.

Formation of urine starts in the glomerulus, where a portion of plasma water is filtered through fenestrated glomerular capillary endothelial cells, a basement membrane, and, finally, filtration slit diaphragms formed by the visceral epithelial cells that cover the basement membrane on its urinary space side. The filtrate collects in Bowman's space, a double-walled invagination that surrounds the glomerular capillaries. From Bowman's capsule the filtered fluid passes into the proximal tubule and begins its passage through the renal tubular system. Small solutes (e.g., sodium, chloride, glucose) are actively filtered with plasma water while larger elements, such as protein, blood cells, and macromolecules, are retained within the glomerular capillaries. The rate of filtration in each nephron is a function of hydrostatic pressure in the glomerular capillaries, hydrostatic pressure from the ultrafiltrate in Bowman's space, mean colloid osmotic pressure in the glomerular capillaries, colloid osmotic pressure of the ultrafiltrate in Bowman's space, and the properties of the filtering membrane. Hydrostatic pressures are the pressures of the fluid against the surface membrane; in the glomerular capillaries, hydrostatic pressure is determined by capillary blood pressure and in

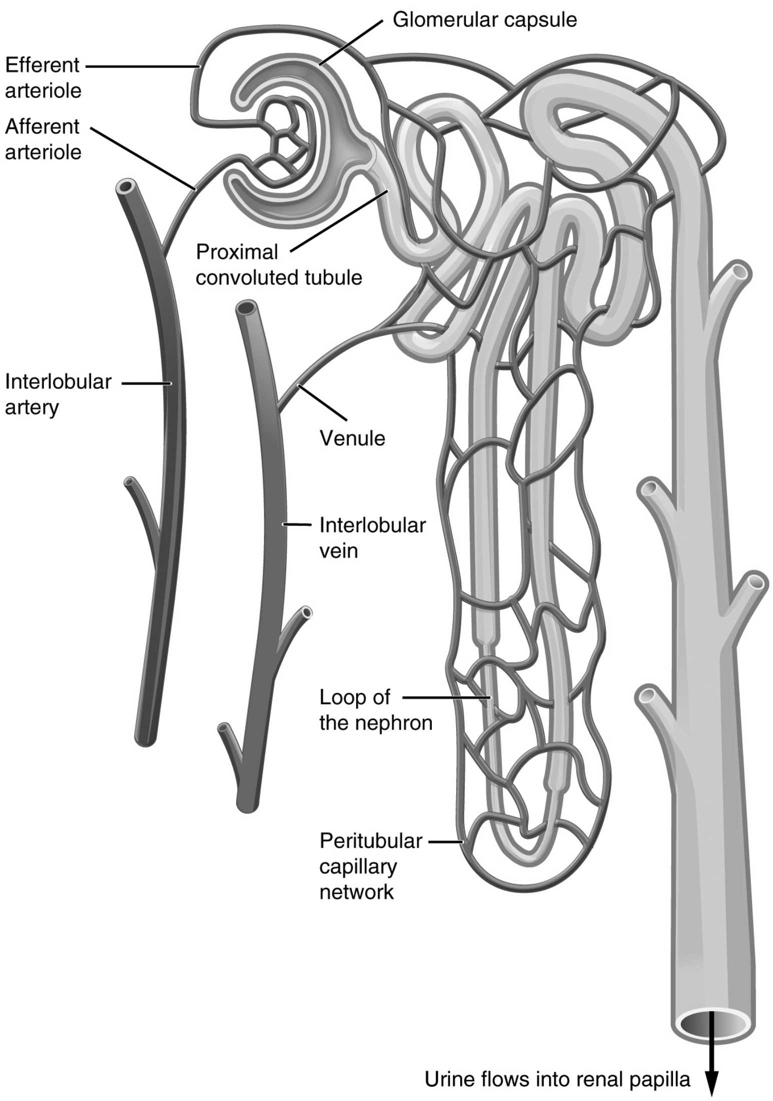

Figure 24.1 Anatomy of the nephron and associated structure. Source: http://cnx.org/contents/14fb4ad7-39a1-4eee-ab6e-3ef2482e3e22@7.30. Used under CC BY 4.0 https://creativecommons.org/licenses/by/4.0/.

the Bowman's space by the pressure of the ultrafiltrate. The primary constituent of the glomerular capillary colloid osmotic pressure is albumin in the plasma and there is little colloidal osmotic pressure in normal urine produced by healthy glomeruli. The colloid osmotic pressure in the plasma is higher than the glomerular filtrate, resulting in an opposing force to filtration. The net filtration pressure (Figure 24.3) is determined by the following relationship:

Net filtration pressure = (blood hydrostatic pressure)
– (blood colloid osmotic pressure)
– (ultrafiltrate hydrostatic pressure)

Changes in glomerular capillary hydrostatic pressure (e.g., hyper- or hypotension), blood colloid osmotic pressure (e.g., hypoalbuminemia), and ultrafiltrate hydrostatic pressure (e.g., albuminuria) can have profound effects on glomerular filtration.

Ultrafiltrate from the glomerulus enters the proximal tubule from Bowman's capsule. By the time urine exits the distal tubule and collecting duct, better than 99% of ultrafiltrate volume will be reabsorbed. Figure 24.4 summarizes the characteristics of reabsorption in broad sections of the renal tubules.

The proximal convoluted tubule (PCT) reabsorbs the majority of sodium (~60% that enters the nephron) by various transporters and water passively follows and is eventually absorbed into the peritubular capillaries by osmosis. Nearly 100% of the glucose, amino acids, and other substances such as vitamins are also reabsorbed in the PCT by various transporters. Animals with hyperglycemia (e.g., diabetes mellitus) may have large amounts of glucose in the nephron, which exceeds the transport capacity of the active transporters to reabsorb from the nephron and glycosuria can occur. Approximately 90% of bicarbonate is reabsorbed in the PCT through the activity of the enzyme carbonic anhydrase (CA) (Figure 24.5).

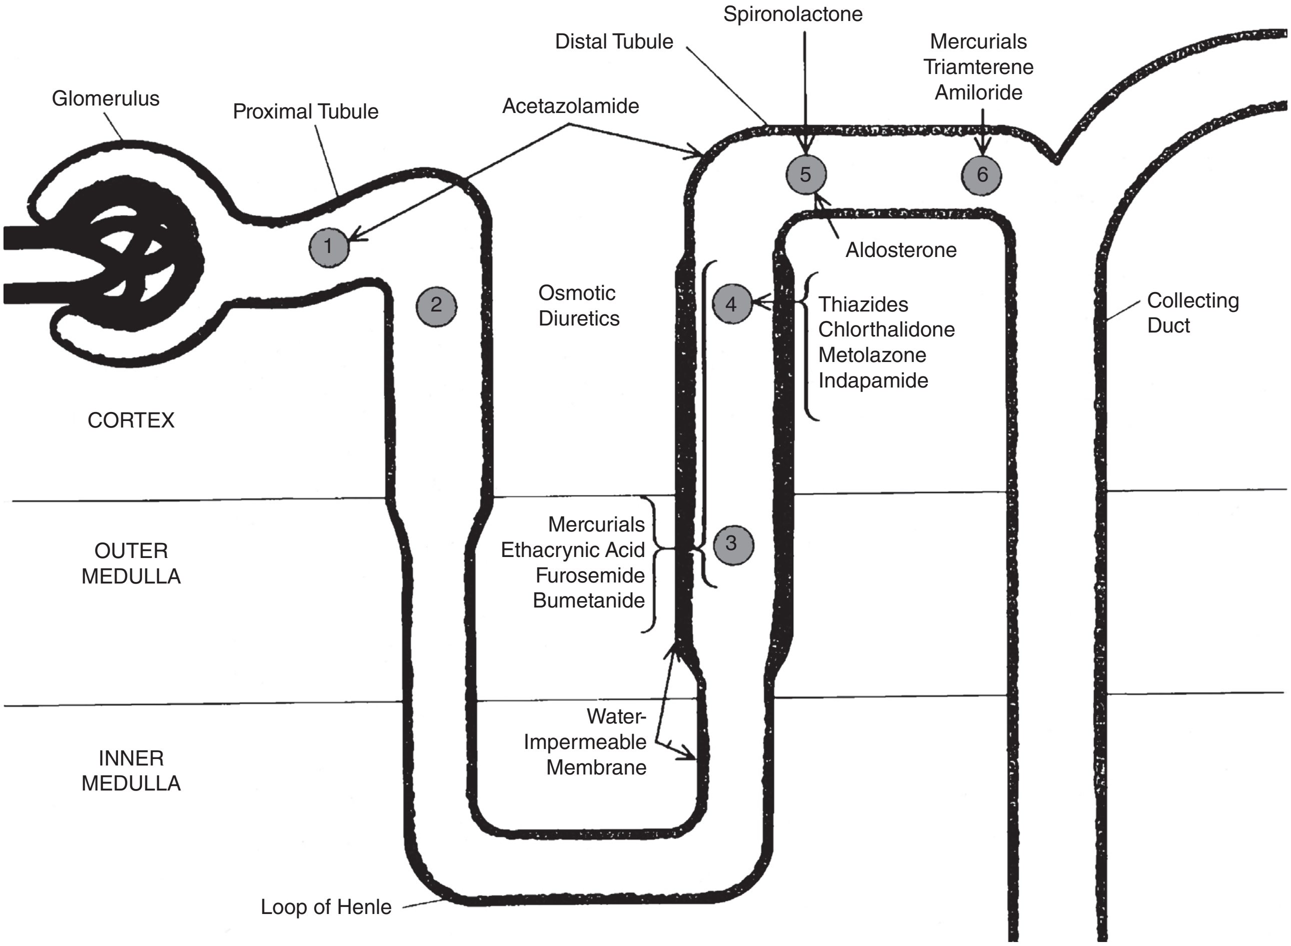

Figure 24.2 Locations within the nephron where diuretic agents exert their effects.

In the nephron bicarbonate combines with a hydrogen ion to produce carbonic acid. Carbonic acid is converted to water and carbon dioxide by CA and carbon dioxide freely diffuses into the PCT cell. Carbon dioxide in the PCT cell then combines with water to form carbonic acid, catalyzed by CA, and the carbonic acid dissociates into bicarbonate and a hydrogen ion effectively transporting bicarbonate from the nephron into the PCT cell. Bicarbonate is then cotransported with sodium to the interstitial fluid where it can diffuse into the peritubular capillaries. Carbonic anhydrase inhibitors (e.g., acetazolamide, methazolamide) exert their primary effects in the PCT, but also have effects on the distal convoluted tubule (DCT).

The Loop of Henle consists of a thick descending loop, thin descending loop, thin ascending loop, and thick ascending loop. Water pores (aquaporins) are present in the thin descending loop that allow water to osmotically move out of the nephron into the interstitial space, which is hyperosmolar (up to four times osmolarity as the original nephron contents). Reabsorption of sodium, potassium, and chloride from the nephron into the renal tubule cell by the sodium-potassium-2-chloride ($Na^+/K^+/2Cl^-$) cotransporter occurs in the thick ascending loop. Sodium is then transported from the cell to the interstitial fluid by the sodium/potassium ATPase and chloride follows sodium through chloride channels to the interstitial fluid (Figure 24.6). The thick ascending loop is impermeable to water. The high osmolarity of the interstitial fluid is thus maintained by the net movement of sodium and chloride from the nephron to the interstitial fluid, which transports a large portion of the sodium and chloride (~35% of the original ultrafiltrate) (Figure 24.7).

The thick ascending limb of the loop of Henle is of particular importance since this is the site of action of the most effective diuretic drugs (i.e., loop diuretics, furosemide). Approximately 25% of filtered solutes are reabsorbed in the loop of Henle, and most of this reabsorption occurs in the thick ascending limb. The thick ascending loop connects with the distal convoluted tubule to make a critical contact with the afferent arteriole through a cluster of specialized epithelial cells, referred to as the macula densa, which monitors the sodium and tubular flow rates and is discussed in more

detail in Section Renin–Angiotensin–Aldosterone System (Figure 24.8). Water, sodium, chloride, bicarbonate, and calcium are reabsorbed in the DCT. Sodium/chloride symporters transport sodium and chloride from the nephron into the DCT cells and are sensitive to the thiazide diuretics (Figure 24.9). Aldosterone enhances sodium and water reabsorption in the DCT and collecting duct by increasing the amount of sodium/potassium ATPase transporters moving sodium out of the nephron and chloride follows along with water. Spironolactone, an aldosterone antagonist, is a diuretic that exerts its effects in the DCT and the collecting duct. Parathyroid hormone (PTH) receptors on the DCT when bound by PTH insert calcium channels on the luminal surface to enhance recovery of calcium from the tubules.

The collecting duct produces the final effects on urine volume based on plasma osmolarity. More water is reabsorbed if the plasma osmolarity is high (e.g., dehydration) and more water is lost if the plasma osmolarity is low (e.g., overhydration). Two main cell types are present in the collecting duct, the principal cells and intercalated cells. The principal cells possess channels for the recovery or loss of sodium and potassium and the intercalated cells secrete or absorb acid and bicarbonate. Intercalated cells are important factors in regulating urine (and plasma) pH through absorption of bicarbonate and excretion of hydrogen ions. Antidiuretic hormone (ADH, arginine vasopressin, or specifically in swine lysine vasopressin) is released from the posterior pituitary gland when plasma osmolarity increases with an effect of increasing water reabsorption in the collecting duct through aquaporins (water channels). Antidiuretic hormone stimulates aquaporin channels to be inserted on the apical side (tubular side) of the principal cells, resulting in water movement from the nephron into the principal cells due to an osmotic gradient. Different aquaporin channels on the basolateral cell membrane allow water movement from the cell into the interstitial space by osmotic movement. The water than diffuses into the peritubular capillaries and reenters the circulation. Alcohol (ethanol) consumption decreases ADH resulting in a diuretic effect,

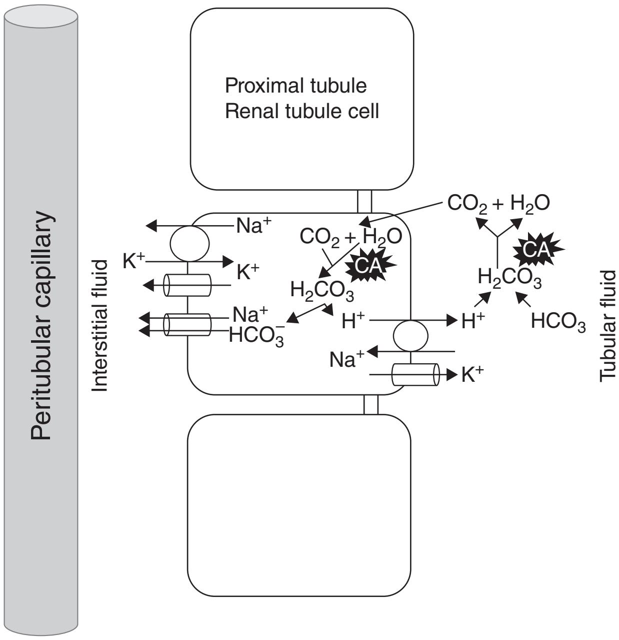

Figure 24.5 Reabsorption of bicarbonate from the proximal convoluted tubule, the primary location of carbonic anhydrase inhibitor effects.

which is observed in animals treated for ethylene glycol toxicity. Aldosterone also produces an effect on the collecting duct, resulting in increased sodium reabsorption from the collecting duct by sodium/potassium channels and sodium/potassium ATPases. Water passively follows sodium, resulting in a net increased reabsorption of sodium and water and net excretion of potassium. Spironolactone administration results in inhibition of aldosterone leading to loss of sodium and water and retention of potassium from the collecting duct and is often referred as a “potassium-sparing” diuretic.

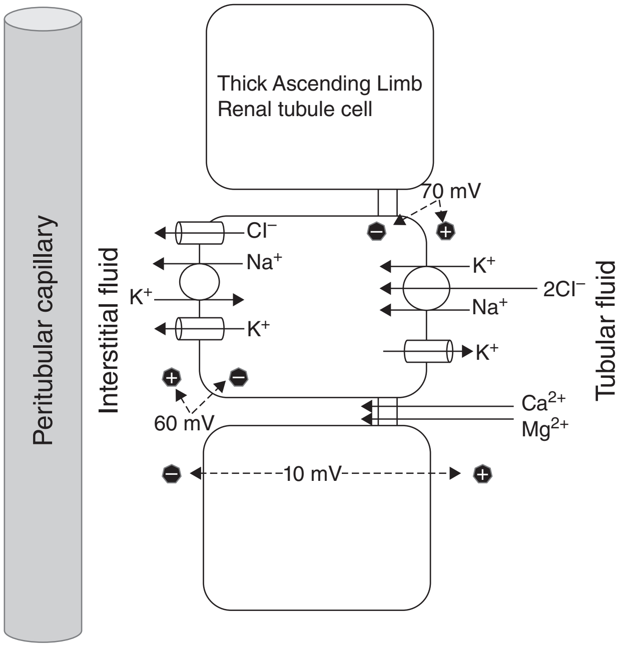

Figure 24.6 Ion movement in the thick ascending loop, the primary location of furosemide effects.

Factors Regulating Renal Function

Renin–Angiotensin–Aldosterone System

The macula densa is located at the junction of the thick ascending limb and distal convoluted tubule and sits between the afferent and efferent arterioles. Together with the juxtaglomerular cells, which produce renin, these components form the juxtaglomerular apparatus (Figure 24.8). Increased reabsorption of Na and Cl detected by the macular densa results in inhibition of renin release into the efferent arteriole by the juxtaglomerular cells through activation of adenosine (A_1) receptors. Conversely, decreased reabsorption of Na and Cl detected by the macular densa stimulates renin release into the efferent arterial through prostaglandins (PGE_2, PGI_2). Renin release is also enhanced when low blood pressure is detected by intrarenal baroreceptors, triggering the release of prostaglandins (PGE_2, PGI_2). Renin release can also be stimulated by an extrarenal mechanism, sympathetic nerve stimulation of β_1 receptors on the juxtaglomerular cells.

Renin release from the juxtaglomerular cells results in a cascade of events known as the renin–angiotensin–aldosterone system (RAAS) (Figure 24.10). Renin converts angiotensinogen, which is released from the liver, to angiotensin I (ATI). Angiotensin I is converted to angiotensin II (ATII) by angiotensin converting enzymes (ACE) located in the lungs. Angiotensin II is a vasoconstrictor, which binds to AT receptors in the vasculature resulting in increased vascular tone and increased blood pressure. Angiotensin II also stimulates the release of aldosterone from the adrenal cortex, which enhances sodium and subsequently water reabsorption in the distal convoluted tubule and collecting ducts, increasing circulating blood volume and blood pressure.

ATII increases vascular tone by multiple mechanisms. ATII produces direct vasoconstriction through AT receptors, resulting in the rapid pressor response. Peripheral sympathetic neurotransmission is enhanced by ATII, resulting in increased release of norepinephrine from nerve terminals. Centrally mediated enhanced sympathetic outflow is also stimulated by ATII. ATII also stimulates catecholamine release from the adrenal medulla.

ATII has affects on renal function. ATII stimulates Na^+/K^+ exchange in the PCT, which increases the reabsorption of Na^+, Cl^-, and $HCO3^+$ (Figure 24.5). The expression of the Na^+/glucose transporter in the PCT

is increased with low concentrations of ATII. The activity of $Na^+/K^+/2Cl^-$ transporter in the thick ascending limb is also enhanced. ATII stimulates the release of aldosterone, which acts at the DCT and collecting ducts to enhance retention of Na^+ and water while increasing elimination of K^+. The vasoconstriction induced by ATII in most cases decreases GFR by affecting the afferent arteriole greater than the efferent arterial. However, during renal hypotension ATII affects the efferent arterial to a greater extent than the afferent, resulting in increased GFR. Administration of ACE inhibitors during renal hypotension increases the risk of acute renal failure.

The RAAS production of ATII is also associated with altered cardiovascular structures. Increased cardiac afterload, due to increased vascular tone, and increased preload, due to aldosterone-mediated sodium and water retention, contribute to cardiac remodeling and hypertrophy. Direct effects of ATII on cardiac myocytes, vascular smooth muscle, and fibroblasts also result

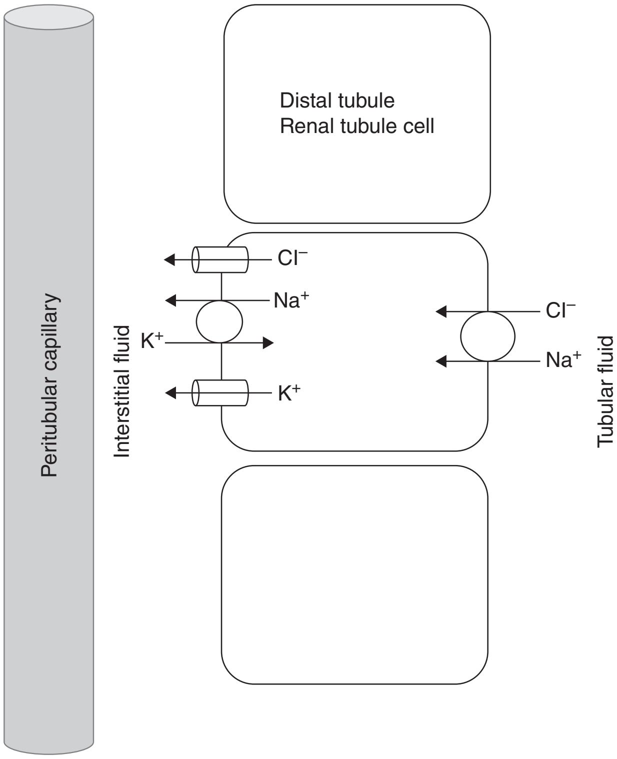

Figure 24.9 Ion movement in the distal convoluted tubule, the primary location of thiazide diuretic effects.

in cardiac hypertrophy and remodeling and vascular remodeling resulting in increased vascular wall thickness and decreased vascular compliance.

Renin release is modulated by feedback inhibition. Angiotensin II stimulates AT receptors on the juxtaglomerular cells decreasing the release of renin and is known as the short negative feedback loop. Increases in blood pressure due to ATII vasoconstriction results in decreased sympathetic tone and subsequently β_1 receptor stimulation. Increases in afferent arterial pressures decrease renin release and is termed the long loop negative feedback.

The RAAS is classically described as an endocrine system response as described above in this section, but locally active and alternative pathways for angiotensin synthesis are present. ACE is present throughout the vascular system in endothelial cells and circulating renin can be stored in the endothelial cells, which can subsequently locally activate the RAAS (Mompeón et al., 2015). Addition tissues (brain, vasculature, heart, adrenal glands, etc.) can produce renin, AT, or ACE that affect local tissue function and structure (Bader and Ganten, 2008). There are also other enzymes that can contribute to the metabolism of angiotensinogen to ATI and ATII. Chymases are enzymes implicated in production of ATII from angiotensin in tissues that can be refractory to ACE inhibitor therapy. There appears to be species-specific

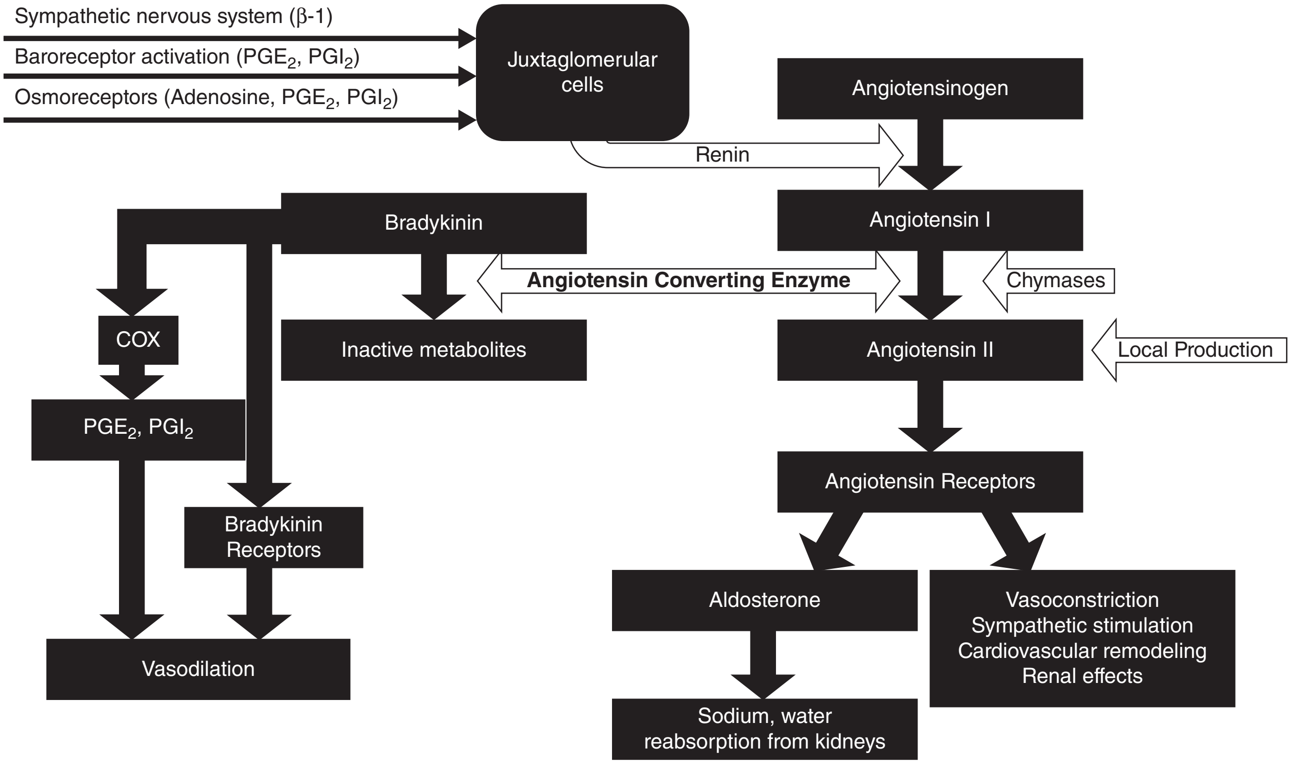

Figure 24.10 Schematic of the renin–angiotensin–aldosterone system.

differences and the overall contribution to ATII formation appears much less than ACE (Aramaki et al., 2003; Campbell, 2012).

Sympathetic Nervous System

The kidneys are innervated by the sympathetic nervous system. Adrenergic α_1-receptor activation results in vasoconstriction of the afferent arterial resulting in decreased blood flow, decreased hydrostatic pressure in the glomerulus, and decreased glomerular filtration rate. Sympathetic β_1 receptors are also located on the macula densa, which stimulate renin release and activation of the RAAS.

Antidiuretic Hormone

Osmoreceptors are specialized cells in the hypothalamus that are sensitive to changes in blood osmolarity (primarily influenced by sodium ion concentration). If blood osmolarity increases, typically due to sodium ingestion or water deprivation), ADH is released from the posterior pituitary with its primary effects on the collecting duct cells to increase water reabsorption from the tubular fluid by inserting aquaporins on the apical (lumen) side of the cells. ADH release is controlled by a negative feedback loop in which low blood osmolarity detected by the osmoreceptors inhibits the release of ADH. Diabetes insipidus is a disease characterized by insufficient production of ADH, resulting in blood hyperosmolarity. Ethanol, which is used in the management of ethylene glycol toxicity, inhibits the release of ADH, which can cause diuresis. ADH is also known as vasopressin as high concentrations result in vasoconstriction.

Cyclooxygenase

Cylcooxygenase (COX) exists as at least two distinct enzymes (COX1, COX2) and is described in detail in Chapter 20. Both COX isoforms are constitutively expressed in the kidneys, but COX2 expression can be induced to produce substantial local effects within the kidneys during periods of hypotension or decreased blood flow. Eicosanoids, products of COX, can exert prominent roles in renal physiology during certain conditions including hypotension (cardiac disease, vasodilation), hypovolemia (dehydration, hemorrhage), and hyponatremia. COXs produce a variety of eicosanoids, including prostaglandin E_2 (PGE_2), prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), prostacyclin (PGI_2), and thromboxane ($TBXA_2$) with resultant effects in the kidney. The eicosanoids can produce afferent arteriole vasodilation (PGE_2, PGI_2) locally antagonizing the effects of systemic vasoconstriction such as sympathetic stimulation, ATII, and vasopressin. Eicosanoids enhance renin release (PGE_2, PGI_2), but renin release is not solely dependent on prostaglandins. Eicosanoids enhance elimination of sodium and water (PGE_2, PGI_2, $PGF_{2\alpha}$) through inhibition of Na^+/K^+ ATPase activity and aquaporin activity. Prostaglandins (PGE_2, PGI2) also produce local vasodilation to maintain medullary blood flow during states of systemic vasoconstriction. Therefore it is not surprising that COX inhibitors can have profound renal effects, with renal adverse effects of nonsteroidal antiinflammatory drugs being the second most common organ system affected with adverse effects.

Renal Epithelial Transport

The presence of anion and cation transporters is essential for most highly protein-bound diuretic drugs to gain access to their site of action, the lumen of the renal tubule. Loop and thiazide diuretics and carbonic anhydrase inhibitors are secreted through the organic acid pathway, and amiloride and triamterene via an organic base transporter (Brater, 1998). Renal insufficiency accompanied by reduced creatinine clearance decreases delivery of diuretic drugs to their secretory site and hence to their site of action. Accumulation of endogenous organic acids during chronic renal failure may result in competition with diuretics for transport at proximal tubule secretion sites (Brater, 1993). Other transporters, including the p-glycoprotein efflux pump, breast cancer resistance protein (BRCP), multidrug and toxin extrusion proteins (MATE1, MATE2-K), and multidrug resistance proteins (MRP2, MRP4), are located in the proximal tubule that contribute to transport of drug into the urine functioning as a mechanism of drug clearance (2013).

Principles of Diuretic Use

Overview

The current therapeutic goal of diuretic use is increased excretion of sodium followed by water. The degree of sodium loss in the urine (referred to as natriuresis or, in combination with chloride, saluresis) varies with the mechanism of action of the drug. All except osmotic diuretics inhibit specific enzymes, transport proteins, hormone receptors, or ion channels that function, directly or indirectly, in renal tubular sodium reabsorption. Although saluresis is the primary clinical goal, diuretics also alter elimination of other ions to varying degrees (e.g., K^+, H^+, Ca^{2+}, Mg^{2+}, Cl^-, HCO_3^-, phosphates) and may affect renal hemodynamics. Diuretic-induced depletion of circulating blood volume may lead to adverse effects such as electrolyte imbalances and dehydration if therapy is not well monitored. Older animals and those with cardiac or renal disease are also at increased risk for adverse effects if diuretic-induced hypovolemia goes untreated. Because these groups are also the primary target groups for diuretic use, rational

use of diuretic drugs is essential. Table 24.1 summarizes selected features of diuretic drugs most commonly used in veterinary medicine.

Edema Formation

The most common indication for diuretic use is removal of tissue edema. Understanding the physiological principles underlying edema formation depends upon an understanding of net capillary filtration. Similar to net filtration pressure in the glomeruli, net capillary filtration, or fluid flux out of a capillary, is dependent upon the plasma colloidal osmotic pressure retaining fluid, and hydrostatic pressure in the arterial capillary forcing fluid out of the capillary through fenestrations and pores. Since the arterial capillary hydrostatic pressure is greater than the plasma colloidal osmotic pressure in most tissues, a small amount of fluid moves from the vasculature into the interstitial space. However, on the venous capillary side, plasma osmotic pressure is greater than the venous hydrostatic pressure and fluid is reabsorbed from the interstitial space into the venous capillary in most tissues, resulting in little net fluid loss into the interstitial space. The lymphatics contribute to fluid absorption from the interstitial space, ensuring no accumulation of fluid in the interstitial space in healthy tissues.

If the fluid movement out of the capillaries exceeds absorption of fluid by venous capillaries and lymphatics, edema results. There can be numerous causes of edema including: lymphatic obstruction (i.e., neoplasia), decreased plasma osmotic pressure (i.e., hypoalbuminemia), and increased venous hydrostatic pressure (i.e., decreased cardiac contractility, excessive intravascular fluid volume). Additionally, the loss of capillary integrity (i.e., inflammation, neurogenic) can result in tissue edema and noncardiogenic pulmonary edema due to head trauma, seizures, and electrocution that occur as a result of poorly understood mechanisms. Therefore the cause of the edema should be identified prior to any therapy, including diuretics.

Congestive heart failure (CHF) is a complex pathophysiological process that begins with decreased cardiac output. The decreased cardiac output and decreased renal blood flow leads to activation of the renin–angiotensin–aldosterone system followed by renal retention of salt and water. High baroreceptor activity causes increased peripheral vascular resistance and increased ADH, which lead to further salt and water retention by the kidneys. Increased central venous pressure caused by increased left ventricular end-diastolic pressures cause increased capillary hydrostatic pressure. All of these factors lead to greater fluid flux out of vessels, resulting in edema related to cardiac disease.

Inhibitors of Carbonic Anhydrase

Chemistry/Formulations

This class of drugs was discovered as a result of the observation that sulfanilamide chemotherapeutic agents were capable of causing metabolic acidosis by inhibition of carbonic anhydrase (CA). Screening of sulfanilamides resulted in identification of compounds whose predominant mechanism of action was CA inhibition. These drugs have been used sparingly in veterinary medicine as diuretics and are more commonly used for ophthalmic purposes as topical formulations. The prototype drug in this class, acetazolamide (Diamox®, Dazamide®), is available in tablets (125 and 250 mg), extended-release capsules (500 mg), and injectable (500 mg per vial). Other CA inhibitors include preparations for oral use, dichlorphenamide (Daranide®) and methazolamide (Neptazane®), and a topical drug, dorzolamide (Trusopt®), for ophthalmic use.

Mechanisms and Sites of Action

Renal Mechanisms

Drugs in this class are active in the CA-rich segments of the nephron, in particular the proximal tubule. Noncompetitive, reversible inhibition of CA located in the luminal and basolateral membranes (type IV CA) as well as in the cytoplasm (type II CA) results in decreased formation of carbonic acid from CO_2 and H_2O (see Figure 24.5 and equation below):

$$HCO_3^- + H^+ \leftrightarrow H_2CO_3 \leftrightarrow H_2O + CO_2$$

Reduction in the amount of carbonic acid yields fewer H^+ within proximal tubular cells. Because H^+ is normally exchanged for Na^+ from the tubular lumen by the Na^+/H^+ antiporter (also referred to as a Na^+/H^+ exchanger or NHE), less Na^+ is reabsorbed and more is available to combine with urinary HCO_3^-. The NHE maintains a low proton concentration in the cell so that $H_2CO_3^-$ ionizes spontaneously to form H^+ and HCO_3^-. This, in turn, creates an electrochemical gradient for HCO_3^- across the basolateral membrane that drives movement of HCO_3^- into the interstitial space. Diuresis is established when water is excreted with sodium bicarbonate that accumulates due lack of CA activity. As sodium bicarbonate is trapped in the urine and eliminated, less HCO_3^- is returned to plasma, and a systemic acidosis eventually develops. As a result of the systemic acidosis, H^+ becomes available, Na^+ reabsorption is reestablished, and diuresis decreases. Continual use of CA inhibitors is therefore self-limiting in terms of diuretic action. Diuresis induced by CA inhibitors is mild due to incomplete inhibition of CA, redundancy of Na^+ transporting systems in the proximal tubule, and rescue of Na^+ by reabsorption later in the distal tubule. Because intracellular K^+ can, to some extent, substitute for H^+ in the Na^+ reabsorption step, CA inhibitors cause enhanced K^+ excretion. As more Na^+ is presented to the distal tubule, the potential for K^+ wasting increases. CA inhibitors also decrease secretion of titratable acids and ammonia in the collecting duct (Jackson, 1996). For this reason, and due to the increased excretion of sodium bicarbonate, urine pH increases despite the decreasing systemic pH associated with CA inhibitor induced acidosis. This class of drugs has little, if any, effect on excretion of Ca^{2+} and Mg^{2+} but does enhance phosphate elimination.

Extrarenal Actions

Other actions of CA inhibitors are related to the wide distribution of CA in body tissues including the eye, gastric mucosa, pancreas, central nervous system (CNS), and red blood cells. The most important therapeutic consequence is associated with CA inhibition in the eye. The ciliary processes of the eye mediate the formation of aqueous humor, which contains an abundance of osmotically active HCO_3^-. This process is CA dependent and, when inhibited, leads to a decreased rate of formation of aqueous humor and subsequent reduction in intraocular pressure. Although not therapeutically relevant in veterinary medicine, CA inhibition in the CNS has been associated with anticonvulsant actions attributed to this class of drugs.

Absorption and Elimination

Limited information is available regarding pharmacokinetics of CA inhibitors in animals. The pharmacokinetics of acetazolamide in dogs administered an extended release product produced an approximately 7-hour half-life with a T_{MAX} at 3 hours (Li et al., 2014). Acetazolamide gains access to the renal tubules via the organic acid secretion pathway. A dose of 22 mg/kg is reported to have an onset of action of 30 minutes, maximal effects in 2–4 hours, and a duration of action of 4–6 hours in small animals (Roberts, 1985). Oral absorption of drugs in this class is appears to be good in dogs. The oral bioavailability of acetazolamide is 25% in horses, with a terminal half-life of 7 hours (Alberts et al., 2000). Acetazolamide is eliminated primarily through the kidneys. The pharmacokinetics of methazolamide has not been reported in dogs, cats, or horses.

Toxicity, Adverse Effects, Contraindications, and Drug Interactions

Although CA inhibitors are sulfonamide derivatives, side effects commonly associated with sulfonamides are not reported or expected (Trepanier, 2004). CNS drowsiness and disorientation may occur as a result of inhibition of CA in the CNS. Because CA inhibitors decrease ammonia excretion, the severity of preexisting hepatic disease may be worsened and hepatic encephalopathy can be induced. Use is also contraindicated in patients with certain electrolyte disturbances (due to K^+ and Na^+ wasting) and those with metabolic or respiratory acidosis. Use in patients with severe pulmonary disease who cannot respond to drug-induced metabolic acidosis with respiratory compensation is also contraindicated. Because CA inhibitors alkalinize the urine, calcium phosphate calculi formation is enhanced, and excretion of weak organic bases is reduced. Rare blood dyscrasias associated with CA inhibitors have also been reported in the human, but not in the veterinary literature.

Therapeutic Uses

The primary indication for use of CA inhibitors is to inhibit production of aqueous humor and reduce intraocular pressure. Topical application of dorzolamide (q 8–12 h) produced similar reductions in intraocular pressure compared to oral methazolamide (5 mg/kg q 12 h) or the combination of topical and oral therapy (Gelatt and MacKay, 2001). The topical CA inhibitors therapy is preferred due to equivalent efficacy, lower potential for adverse effects, and lower cost than systemic administration. Acetazolamide (5–10 mg/kg PO q 8 h) and methazolamide (5 mg/kg PO q 12 h given two to three times daily) have been used previously in dogs for management of glaucoma. CA inhibitors have been administered to patients with hydrocephalus for short-term medical management, often in combination with furosemide, but long-term management with diuretics, in people, is often not successful (Thomas, 2010).

In human medicine, CA inhibitors have been used as an adjunctive therapy for epilepsy and in management of acute mountain (high-altitude) sickness. In both human and veterinary medicine, the use of CA inhibitors as diuretics has limited effectiveness due to the rapid development of tolerance. Theoretically, acetazolamide could be used to manage metabolic alkalosis, but this is not a typical clinical practice in veterinary medicine.

Osmotic Diuretics

Chemistry/Formulations

Osmotic diuretics contain simple solutes of low molecular weight that are typically freely filtered by the glomerulus, undergo limited tubular reabsorption, and are pharmacologically inert. They increase serum and tubular fluid osmolarity resulting in fluid shifts. The most common osmotic diuretic is mannitol, a six-carbon non-metabolized polyalcohol with a molecular weight of 182. Other agents include glycerin, isosorbide, urea, and hypertonic saline solutions. Because mannitol is the most commonly used osmotic diuretic in both human and veterinary medicine, subsequent discussion will focus primarily on this drug. Concentrated mannitol (15–25%) may crystallize at cooler temperatures, in which case the drug can often be resolubilized by warming the solution. Prior to administration, the solution should be cooled and any remaining crystals removed using an in-line intravenous (IV) filter. There are no veterinary-approved mannitol formulations available. For IV use in animals, the human formulations are used. Human products (Osmitrol®, Resectisol®) range from 5% (275 mOsm/l) to 25% (1375 mOsm/l) and are available for IV administration.

Mechanisms and Sites of Action

Hyperosmolar solutions exert part of their effects by establishing an osmotic gradient between plasma and extravascular fluid compartments resulting in fluid movement into the plasma. Acute effects of this gradient include decreases in hematocrit, blood viscosity, plasma sodium, plasma pH, and, to some degree, the volume of solid organs. Hence, parenchymal dehydration and acute hemodilution are theoretically related as long as the osmotically active particles are effectively separated by a relatively solute-impermeable barrier.

Renal Mechanisms

Initially, osmotic diuretics were thought to act primarily at the level of the proximal tubule by limiting the movement of water from the lumen into the interstitial space. Water retained in the tubular lumen diluted concentrations of sodium and other ions, reduced ion reabsorption, and promoted diuresis. It is now held that osmotic diuretics, in particular mannitol, have effects throughout the length of the tubule, with the most prominent action occurring in the loop of Henle. Sodium reabsorption is markedly reduced in the descending and thin limbs of the loop of Henle, as determined by studies in dogs and rats. Sodium load to the thick ascending limb of the loop of Henle and to the distal tubule is consequently increased, but the nephron fails to recapture the increased loads of salt and water. As demonstrated in the dog, sodium reabsorption is also thought to be directly inhibited in medullary collecting ducts (Better et al., 1997).

Other reported renal effects of mannitol include increases in cortical and medullary blood flow due to a decrease in renal vascular resistance, impairment of urinary concentration, reduction in medullary tonicity (also known as medullary washout), an increase in GFR during renal hypoperfusion (may vary according to species), and an increase in urinary excretion of other electrolytes (e.g., K^+, Ca^{2+}, Mg^{2+}, phosphate, bicarbonate) (Better et al., 1997). Mannitol may also prompt the release of atrial natriuretic factor and vasodilatory prostaglandins and inhibition of renin release.

Extrarenal Mechanisms

The actions of mannitol extend beyond the renal effects and include changes in blood rheology, direct transient effects on vascular tone, and increases in cardiac output. In addition to decreasing the hematocrit by hemodilution, mannitol decreases the volume, rigidity, and cohesiveness of red blood cell membranes. The combination of reduced viscosity and reduced mechanical resistance presumably leads to enhanced blood flow. Mannitol-induced increases in cardiac output are thought to be related to reduced peripheral resistance and reduced afterload, a transient increase in preload, and mild positive inotropy. Mannitol may also exert a cytoprotective effect by acting as an oxygen-free radical scavenger (Paczynski, 1997).

Absorption and Elimination

Mannitol is not metabolized and is handled as an inert substance by the body. Studies in dogs and humans indicate that mannitol distribution and elimination follow a two-compartment model (Cloyd et al., 1986; Rudehill et al., 1993). The distribution half-life of intravenously administered mannitol is measured in minutes. Elimination half-life is dose dependent and ranges from 0.5 to

1.5 hours for doses between 0.25 and 1.5 g/kg. Mannitol is eliminated rapidly by the kidneys unless renal function is impaired. As a result, penetration of mannitol into tissues is limited by rapidly falling plasma concentrations. Mannitol is administered intravenously in a slow bolus over 15–30 minutes. Glycerin and isosorbide are administered orally. Of the available osmotic diuretics, only glycerin is eliminated by biotransformation.

Adverse Effects and Drug Interactions

Acute Adverse Effects

Pulse pressure and mean arterial blood pressure usually increase transiently with mannitol administration. However, acute hypotensive, hyponatremic effects of mannitol administration have been reported, especially subsequent to rapid infusion in dehydrated individuals. The mechanism for this acute vasodilatory effect is not well understood, but the problem can largely be prevented by appropriate rates of administration (0.25–1.5 g/kg over 15–30 min). Acute hyponatremia may account for the nausea and vomiting that are sometimes observed with mannitol infusion. Rapid expansion of plasma volume related to attraction of fluid into the vascular compartment may precipitate CHF or pulmonary edema in certain patient populations. However, because the drug is cleared rapidly this problem is not common unless renal function is impaired or underlying cardiac disease is present.

Dehydration and Electrolyte Disturbances

Because the ratio of the volume of fluid eliminated in urine to the volume of mannitol administered is high, care should be taken to avoid hypertonic dehydration. Circulating plasma volume tends to be preserved as hypertonic dehydration develops, making it harder to clinically detect that a problem exists. The presence of dehydration and significant hypernatremia should be closely monitored using body weight, urine output, and other clinical parameters. In addition to hypertonic dehydration, loss of other electrolytes, including potassium, phosphate, and magnesium, can lead to clinically significant cardiac arrhythmias and neuromuscular complications.

Hyperosmolar State and Osmotic Compensation

The phenomenon of osmotic compensation occurs when cells respond to prolonged treatment with a hyperosmolar agent by increasing the presence of intracellular, idiogenic osmoles. Compensation is thought to occur rapidly when the osmolality of plasma is increased by 25 mOsm/kg or more above normal. Newly generated, osmotically active intracellular particles counteract the dehydrating effect of hyperosmolar plasma. Osmotic compensation can limit therapeutic effectiveness by decreasing the osmotic gradient from tissue to plasma. Increased intracellular osmolarity may also promote conditions, especially in the brain, where iatrogenic edema may occur. The risk of edema formation is increased if a hyperosmolar state is reversed rapidly, leaving the intracellular osmoles as the most osmotically active site. To prevent this complication, the duration of return of plasma to normal osmolality should be approximately equal to the duration of the hyperosmolar state.

Contraindications

The use of mannitol in patients with ongoing intracranial hemorrhage, anuric renal failure, severe dehydration, or pulmonary congestion or edema is contraindicated. Adequate fluid therapy should be administered to dehydrated animals prior to administration of mannitol. Mannitol should not be added to whole-blood products unless at least 20 mEq/l of sodium chloride is added to the solution; otherwise, pseudoagglutination may occur.

Therapeutic Uses

Mannitol is used in the prophylaxis and treatment of renal failure, for the reduction of intracranial and intraocular pressure, and with other diuretics to mobilize edema. For reasons already discussed, short-term use of mannitol is most effective to prevent adverse effects and decreased therapeutic efficacy.

Prophylaxis of Acute Renal Failure

Anuric patients should not be routinely treated with mannitol, although a small (0.25–0.5 g/kg), single test dose may be used to try and induce diuresis. Administration of mannitol to patients with renal dysfunction must be done cautiously to prevent problems associated with decreased elimination and prolonged hyperosmolarity. Acute renal failure (ARF) may be caused extrinsically (pre- and postrenal failure) or intrinsically, often associated with acute renal tubular necrosis (ATN). Mannitol has been found to be effective in limiting the decrease in GFR caused by ATN if administered before the ischemic insult or exposure to nephrotoxins. Protection of tubules from necrosis may be due to dilution of nephrotoxic substances, reduction of swelling of tubular elements, or removal of tubular casts that are obstructing urine flow. In human medicine, mannitol has been shown to be clearly beneficial in the preservation of kidneys for transplant and for decreasing the incidence of posttransplant ARF. Fewer data are available to support the general value of mannitol for treatment of ARF outside the area of transplantation (Better et al., 1997). In vascular and open-heart surgery, prophylactic mannitol maintains urine flow but not GFR. Some evidence suggests that mannitol administration in patients with established ATN may increase the conversion of oliguric to nonoliguric patients (Levinsky and Bernard, 1988).

Reduction of Intracranial Pressure

Osmotherapy has been used for decades to decrease intracranial pressure (ICP). Reduction in ICP is rapid and usually appears within minutes of completion of administration, with maximum effects within the hour. Several theories have been formulated to account for the effectiveness of mannitol in reducing ICP. The osmotic theory holds that brain shrinkage occurs as a result of osmotically driven movement of fluid from tissue and into the vascular compartment. Sensitive, high-resolution imaging methods seem to support the significance of osmotically induced changes in brain water content (Betz et al., 1989). The hemodynamic theory of ICP reduction states that cerebral blood volume is decreased as a result of decreased blood viscosity and increased cerebral perfusion pressure, both of which act to enhance oxygen delivery to the brain. Increased oxygen delivery to the brain is thought to trigger a compensatory reduction in vascular caliber and secondarily a reduction in cerebral blood volume. Detractors of this idea suggest that mannitol is just as likely to decrease blood viscosity as a result of hemoconcentration secondary to hypertonic dehydration. While attention to fluid replacement should prevent dehydration, it has recently been suggested that alternative agents, such as hypertonic saline, are safer and equally effective at reducing ICP (Raslan and Bhardwaj, 2007). Hypertonic saline has been shown to establish a strong transendothelial osmotic gradient but without the tendency to reduce intravascular volume (Prough and Zornow, 1998). Finally, the diuretic theory of ICP reduction suggests that mannitol-induced decreases in central venous pressure translate directly to decreases in ICP due to the valveless communication between the central venous system and the jugular drainage system. This effect may be more important in sustaining, rather than inducing, a decrease in ICP (Paczynski, 1997). Regardless of the theory, mannitol has been used for temporary reduction of ICP in patients with a variety of intracranial lesions as well as those with spinal cord trauma and edema. Evidence of ongoing intracranial hemorrhage is considered a contraindication for mannitol administration. Rebound increases in intracranial pressure have been observed with mannitol in 10–20% of human patients (Node and Nakazawa, 1990) and may be due in part to mannitol movement through the blood–brain barrier (Raslan and Bhardwaj, 2007).

Other Uses

Osmotic diuretics have also been used successfully to control intraocular pressure during acute glaucoma attacks and to reduce intraocular pressure before or after ophthalmic surgery. Decreases in intraocular pressure occur by loss of intraocular water to hyperosmolar plasma. As the vitreous shrinks, the lens moves posteriorly and the iridocorneal angle opens, improving drainage from the eye. The duration of action depends upon the degree to which the osmotic diuretic is excluded from ocular fluids. Mannitol is reported to increase retinal oxygen tension and is used at a dose of 1–2 g/kg at a rate of 1 ml/kg/min to reduce intraocular pressure in dogs. Although still useful for decreasing intraocular pressure due to glaucoma, other therapies including topical carbonic anhydrase inhibitors (i.e., dorzolamide), β_1 antagonists (i.e., timolol), and prostaglandin analogues (i.e., latanoprost) are the preferred therapies.

Inhibitors of $Na^+/K^+/2Cl^-$ Symport (Loop or High-Ceiling Diuretics)

Drugs belonging to this class are among the most effective and the most commonly prescribed diuretics, and all share a common mechanism of action. By blocking a key sodium transport mechanism in the thick ascending limb of the loop of Henle (hence the name loop diuretic), these drugs inhibit reabsorption of up to 25% of the filtered sodium load. Nephron segments distal to the thick ascending limb (TAL) are incapable of reabsorbing the additional solute, leading to a marked (or high-ceiling) natriuresis and diuresis. Because furosemide (Salix®, Disal®) is by far the most commonly used diuretic in veterinary medicine, the remaining discussion will focus primarily on this drug (also referred to as frusemide). Other drugs in this class include ethacrynic acid (Edecrin®), bumetanide (Bumex®), and the most recent addition approved in the United States, torsemide (Demadex®).

Chemistry/Formulations

Except for ethacrynic acid, the structurally diverse drugs in this class are sulfonamide derivatives; however, they are not subject to the same adverse effects as sulfonamide antimicrobials. Furosemide is light sensitive and stable under alkaline conditions; the veterinary injectable preparations (Salix or generic; 50 mg/ml) have a light yellow color, whereas the human injectable (Lasix®; 10 mg/ml) should not be used if it appears yellow. A wide range of veterinary preparations of furosemide are available, including oral tablets approved for use in dogs and cats (12.5 mg, 50 mg), oral solution approved for use in dogs (10 mg/ml), large-animal boluses approved for use in cattle (2 g/bolus), and injectable (5%) approved for use in dogs, cats, horses not intended for food, and cattle.

Milk and slaughter withdrawal time for both oral and injectable formulations for cattle is 48 hours. Bumetanide (Bumex® is supplied in 0.5, 1, and 2 mg tablets and as a 0.25 mg/ml parenteral injection. Bumetanide is approximately 40 to 50 times more potent than furosemide in the dog. Torsemide (also torasemide) (Demadex) is supplied as 5, 10, 20, and 100 mg tablets and in 2 or 5 ml ampules containing 10 mg/ml for intravenous administration. Torsemide dosage in the dog has been estimated at approximately one-tenth the human dose but the drug has not been well studied in dogs and cats (Kittleson and Kienle, 2007).

Mechanisms and Sites of Action

Renal Effects

Drugs in this class block the Na^+-K^+-$2Cl^-$ symporter in the TAL by binding to the Cl^- binding site of the transporter protein (Figure 24.6). All of these drugs must be actively secreted into the tubular lumen by an organic acid pathway in order to reach and inhibit the luminal symporter. A high degree of protein binding (>95%) limits glomerular filtration of furosemide and other loop diuretics, making tubular secretion essential.

The mechanism involved in Na^+ reabsorption in the TAL depends upon Na^+/K^+ ATPase activity in the basal membrane of tubular cells, creating an electrochemical gradient. The low intracellular sodium concentration induced by the Na^+/K^+ATPase drives the absorption of sodium, along with potassium and chloride, from the tubular fluid by $Na^+/K^+/2Cl^-$ symporter located in the luminal membrane. Recycling of the potassium back into the tubular fluid is accomplished by the potassium channels on the luminal membrane. Chloride channels on the basolateral side efflux chloride from the intracellular compartment. Basolateral Cl^- conductance and luminal K^+ conductance determine membrane voltage. The polarity of K^+ and Cl^- conductances results in a lumen-positive transepithelial voltage. This voltage drives cations (Ca^{2+} and Mg^{2+}) between tubular cells via the paracellular shunt pathway. When loop diuretics block the $Na^+/K^+/2Cl^-$ symporter, Cl^- concentrations in the cell fall, the cell becomes hyperpolarized, transepithelial voltage is disrupted, and paracellular cation reabsorption is blocked (Bleich and Gregor, 1997). Because renin-producing cells in the area of the macula densa generate part of their membrane voltage via Cl^- channels, the new Cl^- equilibrium also depolarizes these cells and enhances the secretion of renin.

Loop diuretics interfere with establishment of a hypertonic medullary interstitium (due to impaired sodium reabsorption) and disrupt the countercurrent mechanism. Hence, these drugs block the kidney's ability to concentrate and dilute urine appropriately. Inhibitors of the $Na^+/K^+/2Cl^-$ symporter also inhibit Ca^{2+} and Mg^{2+} reabsorption in the TAL by disruption of the transepithelial potential difference. Some loop diuretics, notably furosemide, also have weak carbonic anhydrase-inhibiting activity that leads to enhanced urinary excretion of HCO_3^- and phosphate. All $Na^+/K^+/2Cl^-$ symporter inhibitors increase the urinary excretion of K^+ and H^+ by presenting a greater load of Na^+ to the distal tubule. Sodium is reabsorbed while K^+ and H^+ are excreted.

Nonsteroidal antiinflammatory drugs (NSAIDs) inhibit the diuretic, natriuretic, and chloruretic responses to furosemide. Furosemide enhances production of prostaglandin E2 (PGE_2), which in turn inhibits chloride and sodium reabsorption in the TAL. In the presence of NSAIDs, PGE_2 production is blocked, and furosemide-induced diuresis is decreased (Kirchner, 1987). In the absence of volume depletion, loop diuretics generally increase and redistribute total renal blood flow. The mechanism for this effect is thought to be related to prostaglandins, and the effect is diminished or blocked in the presence of NSAIDs (Data et al., 1978). Furosemide-induced hemodynamic changes correlate with an increase in urinary excretion of PGE_2.

Extrarenal Effects

Furosemide causes extrarenal hemodynamic effects that include increased venous compliance and decreased right atrial pressure, decreased pulmonary artery pressure, decreased pulmonary artery wedge pressure, and decreased pulmonary blood volume (Hinchcliff and Muir, 1991). Prostaglandins are thought to account for the acute increase in systemic venous capacitance and subsequent decrease in left ventricular filling pressure. All of these effects are dependent upon the presence of a functional kidney and the uninhibited production of prostaglandins. In the isolated rabbit heart, furosemide has also been reported to exert a mild negative inotropic effect that is prostaglandin dependent (Feldman et al., 1987). Similarly, prostaglandins are important for furosemide's effects in horses since phenylbutazone decreased its diuretic and vascular responses (Hinchcliff et al., 1995).

Inhaled furosemide in humans has been shown to protect against the early response to inhaled allergens and to prevent exercise-induced bronchoconstriction (Bianco et al., 1988, 1989). Furosemide may prevent bronchoconstriction in part by inhibiting release of inflammatory mediators from lung cells (Anderson et al., 1991). Pulmonary gas exchange is reportedly improved by furosemide in experimental pulmonary edema. Furosemide also reduces the rate of pulmonary transvascular fluid filtration through a reduction in pulmonary vein pressure (Demling and Will, 1978).

Absorption and Elimination

Furosemide is approximately 77% bioavailable in dogs and has an elimination half-life of about 1 hour following an IV dose of 5 mg/kg (Hirai et al., 1992). The absorption of orally administered furosemide takes place mainly in the upper parts of the canine gastrointestinal tract, decreasing rapidly across the jejunum. Peak diuretic effects of an IV dosage of furosemide in the dog are reported at approximately 30 minutes and following oral dosing at about 1–2 hours. The rate of urinary furosemide excretion, more so than the concentration of plasma furosemide, has been found to closely correlate with diuretic response in dogs. As in humans, the relation between the natriuretic response and the concentration of diuretic in the urine (at the site of action) is represented by a typical sigmoidal concentration–response curve. The shape of the curve suggests that a threshold quantity of drug must be achieved at the site of action in order to elicit a response and that a maximal dose can be identified that yields a maximal response. Beyond that maximal dose, the curve plateaus, and limited additional benefits are derived from dose increases (Brater, 1998; Hirai et al., 1992). Because intermittent doses produce a brief effect in dogs and higher doses do not produce a greater effect, the use of a constant-rate infusion (CRI) has been explored. In dogs, a loading dose of 0.66 mg/kg is followed by a CRI of 0.66 mg/kg/h × 8 hours. This results in greater natriuresis, calciuresis, and diuresis than with intermittent treatment (Adin et al., 2003).

Elimination half-life of IV furosemide in the horse is similar to that in the dog and, in the absence of renal impairment, is slightly less than 1 hour. Furosemide is typically administered IV or IM three to four times daily to horses. A study comparing oral and IV administration of the drug determined that systemic availability of furosemide given orally is poor, erratic, and variable among horses. Median systemic bioavailability was low and, at a dose of 1 mg/kg PO, diuresis was not induced (Johansson et al., 2004). In a study comparing CRI to intermittent administration of furosemide in the horse, CRI of the drug produced more uniform urine flow, decreased fluctuations in plasma volume, and suppressed renal concentrating ability throughout the study. Although potassium, calcium, and chloride excretion were higher with CRI than intermittent administration, CRI was preferred if profound diuresis was required in the horse (Johansson et al., 2003).

In humans and other animals, including the dog and horse, approximately 50–60% of a furosemide dose is excreted unchanged in the urine, and the remaining drug is conjugated to glucuronic acid in either the kidney, the liver, or other extrahepatic site (Brater, 1998; Dyke et al., 1998).

Plasma half-life in patients with renal insufficiency is prolonged, and dosage adjustments should be made. Binding of furosemide to excessive amounts of albumin (>4 g/l) in the urine decreases the amount of unbound, active drug and diminishes the diuretic response. In human patients with nephrotic syndrome, doses of two to three times normal are recommended to provide sufficient amounts of active drug to block the $Na^+/K^+/2Cl^-$ symporter.

In humans, bumetanide and torsemide are metabolized in large part by the liver, and so dosage generally does not need to be adjusted for renal disease. Bumetanide's potency in the dog is, in part, explained by limited biotransformation. In addition, renal uptake of bumetanide is greater than furosemide and the drug has a more marked effect on sodium transport in the ascending limb of the Loop of Henle. Approximately 67% of bumetanide in dogs is eliminated unchanged in the urine and feces (Schwartz, 1981). Oral bioavailability of these drugs is much more predictable than that of furosemide and in humans ranges from 80 to 100% (Brater, 1998).

Toxicity, Adverse Effects, Contraindications, and Drug Interactions

Most adverse effects of furosemide administration are related to abnormalities of fluid and electrolyte balance. Extracellular volume depletion and hyponatremia may lead to reduced blood pressure and diminished organ perfusion. Most at risk for adverse effects related to volume depletion are patients with renal disease (may decrease GFR, increase prerenal azotemia, and, possibly, cause tubular necrosis), cardiac disease (stroke volume and cardiac output may decrease), and hepatic disease (precipitation of hepatic encephalopathy). As noted previously, $Na^+/K^+/2Cl^-$ symporter inhibitors deliver an increased load of Na^+ to the distal tubules, resulting in a renin–angiotensin–aldosterone-driven increase in excretion of K^+ and H^+ in exchange for Na^+. Hypochloremic alkalosis and hypokalemia may result. Risk factors for cardiac dysrhythmias related to diuretic-induced hypokalemia include inadequate dietary intake of K^+, concurrent administration of cardiac glycosides, and additional electrolyte imbalances. A common cause of anorexia in CHF patients is digitalis toxicity, and risk of arrhythmias is increased in these patients if hypokalemia is present. Deficiencies in Mg^{2+} and Ca^{2+} may also be caused by diuretic-enhanced excretion of these substances. Serum electrolyte levels should be monitored in patients receiving ongoing diuretic therapy, especially if risk factors exist related to appetite, diuretic dosage, or severity of disease.

Ototoxicity, which is usually transient, has been described primarily with ethacrynic acid and less often with all other loop diuretics. In veterinary medicine, ototoxicity may be of greatest concern in treatment of cats with high-dose IV regimens. Other adverse effects reported with use of loop diuretics include gastrointestinal disturbances, bone marrow depression, and hyperglycemia. Hyperglycemia may be related to impairment of proinsulin-to-insulin conversion associated with diuretic-induced decreases in K^+ levels. Patients hypersensitive to sulfonamides may also be hypersensitive to furosemide since this drug contains a sulfonamide moiety. Diuretic-induced depletion of water-soluble vitamins may occur, and supplementation of B-complex vitamins has been recommended for animals receiving continuous diuretic therapy (Keene and Rush, 1995).

Loop diuretics are contraindicated in animals with severe fluid and electrolyte disturbances or anuria that does not respond to test doses of diuretics.

Drug interactions may occur when furosemide is administered with theophylline/aminophylline (enhanced effects due to theophylline-induced diuresis), aminoglycosides or cisplatin (enhanced ototoxicity and, if volume depleted, nephrotoxicity), digitalis glycosides (diuretic-induced hypokalemia may increase risk of arrhythmias), aspirin or other anticoagulants (anticoagulant activity increased), neuromuscular blockers (alteration in extent of muscle relaxation), corticosteroids (enhanced potassium wasting), insulin (alteration of insulin requirements associated with hyperglycemic effects), lithium and propranolol (increased plasma levels), probenecid (competition for secretion of diuretic into tubular lumen leading to decreased diuretic effect), NSAIDs (as previously described, decreased diuretic effects), and thiazides (synergistic diuretic activity).

Therapeutic Uses

Furosemide is used in small animals for treatment of edema of cardiac, hepatic, or renal origin. In general, the dose of drug in dogs (1–3 mg/kg every 8–24 hours PO for chronic use; 2–5 mg/kg every 4–6 hours IV, IM, SC) is higher than that used in cats (1–2 mg/kg every 12 hours up to 4 mg/kg every 8–12 hours IV, IM, SC, PO) (Ware, 1998). Furosemide is also used to establish diuresis in renal failure and to promote excretion of other substances, including elevated electrolytes such as Ca^{2+} and K^+. In large animals, furosemide has been used to treat edema in cattle and edema and exercise-induced pulmonary hemorrhage (EIPH) in horses. A general dose of 0.5–1 mg/kg twice daily or as needed to control edema has been recommended in large animals (Reef and McGuirk, 1996). Benefits of furosemide use for treatment of EIPH remain controversial (see Section Exercise-Induced Pulmonary Hemorrhage). Specific state guidelines should be consulted for details of furosemide use (dose, frequency, allowable levels) in racing animals.

Diuretic effects of orally administered torsemide (0.3 mg/kg) and furosemide (3 mg/kg) were compared in dogs and cats (Uechi et al., 2003). Both furosemide and torsemide increased urine volume but the effects of furosemide peaked at 2–3 hours and dissipated by 6 hours while the effects of torsemide peaked at 2–4 hours but persisted for 12 hours in normal dogs, dogs with mitral regurgitation, and cats with experimentally induced left ventricular concentric hypertrophy. It was noted that torsemide decreased urine potassium excretion in study dogs with mitral regurgitation. In a previous study, the ratio of sodium to potassium excretion was found to be 20:1 for torsemide and 10:1 for furosemide (Ghys et al., 1985).

Renal Insufficiency

Decreased GFR and decreased delivery of drug to the tubular site of action and site of elimination in renal insufficiency results in decreased efficacy and increased half-life of furosemide. A sufficiently high dose of drug must be administered to attain an effective amount of drug at the site of action. For the dog, furosemide doses starting at 2 mg/kg IV and increasing in 2 mg/kg increments every hour for 3 hours may be used to try and induce diuresis in severe renal insufficiency. Once a maximal dosage is reached (approximately 6–8 mg/kg), exceeding this amount is not advantageous based on the sigmoidal shape of the fractional sodium excretion curve. In all cases, fluid deficits should be addressed prior to furosemide therapy.

Cardiogenic or Pulmonary Edema

Furosemide has been widely used to reduce extracellular volume and minimize venous and pulmonary congestion in chronic and acute CHF. In humans, beneficial effects in congestive heart failure are noted prior to induction of diuresis suggesting vascular effects are important components of furosemide benefits in patients with pulmonary edema. Human patients with CHF do not require large dosages since furosemide is adequately delivered to the tubular fluid. However, because renal responsiveness to loop diuretics appears to be decreased in these patients, increased frequency of administration has been recommended (Brater, 1998). Diuretics have traditionally been considered front-line therapy for the treatment of chronic CHF in small animals, and furosemide is reported to be the most frequently used drug for this purpose (Goodwin and Hamlin, 1993; Watson and Church, 1995). Despite the popularity of furosemide, human studies have revealed that CHF patients controlled on loop diuretics alone deteriorate more quickly than those treated concurrently with either angiotensin-converting enzyme (ACE) inhibitors or digoxin. Use of furosemide alone is thought to enhance early activation of the renin–angiotensin–aldosterone system, with detrimental effects on long-term prognosis (Swedberg et al., 1990). Current recommendations include furosemide for treatment of more advanced stages of heart failure in patients already receiving ACE inhibitors, digoxin, or both. Furosemide remains a drug of choice for treatment of acute cardiogenic pulmonary edema. Within the context of severity and chronicity of disease, the lowest effective dosage and frequency of furosemide administration should be determined by observation of clinical signs and consideration of owner observations.

Exercise-Induced Pulmonary Hemorrhage

Exercise-induced pulmonary hemorrhage**,** or bleeding from the lungs as a consequence of intense exercise, occurs in horses engaged in a variety of athletic activities. The problem has been best studied in racing horses, particularly Thoroughbreds. A consensus statement on EIPH has been released by the American College of Veterinary Internal Medicine (Hinchcliff et al.,2015).

In most studies, furosemide has been found to reduce right atrial, pulmonary arterial, and pulmonary wedge pressures in exercising horses. Some studies suggest that changes in pulmonary pressures caused by furosemide are due to reduction in plasma and blood volume and not to direct effects of the drug on the pulmonary vasculature. Furosemide produces a rapid reduction in blood and plasma volume, which has been shown in the horse to be essential for subsequent reduction in pulmonary pressures (Hinchcliff et al., 1996). Furthermore, administration of polyionic fluids in an amount equal to the volume lost in urine restores furosemide-induced decreases in right atrial pressure and blood volume in the horse (Rivas and Hinchcliff, 1997). Furosemide administration 4 hours prior to exercise has been found to significantly decrease pulmonary capillary hypertension, which is thought to correlate with decreased risk of EIPH. Administration of the drug at shorter intervals prior to exercise did not result in more effective attenuation of exercise-induced pulmonary capillary hypertension (Magid et al., 2000). Combination of furosemide with either clenbuterol (Manohar et al., 2000) or pentoxifylline (Manohar, 2001) have not been found to enhance the pulmonary hemodynamic efficacy of furosemide in EIPH.

Data from additional studies leave open the question of direct effects of furosemide on pulmonary pressures and mechanics in EIPH. In one study horses treated with NSAIDs (phenylbutazone and flunixin) prior to administration of furosemide followed by exercise did not show reductions in pulmonary and right atrial pressures (Olsen et al., 1992). In a subsequent study these effects could not be reproduced (Manohar, 1994). Differences in the studies may be related to drug dosages, time of administration, amount of diuresis, and degree of cyclooxygenase inhibition. While it is accepted that NSAIDs decrease the diuretic and vascular responses to furosemide, it is as yet unresolved whether these drugs mitigate furosemide-induced reductions in pulmonary and right atrial pressures. It is also not clear whether the magnitude of reduction of pulmonary capillary transmural pressure with furosemide is sufficient to prevent capillary rupture in exercising horses (Soma and Uboh, 1998). This is consistent with clinical observations that furosemide reduces, but does not completely eliminate, pulmonary hemorrhage in exercising horses.

Administration of furosemide to racing animals is thought to enhance their performance, although this conclusion remains somewhat controversial. Use of furosemide in racing Thoroughbreds, Quarter Horses, and Standardbreds is estimated at 74.3, 19, and 22.5%, respectively (Hinchcliff, 1999). A cross-sectional study concluded that Thoroughbreds receiving furosemide raced faster, earned more money, and were more likely to win or finish in the top three positions than unmedicated horses (Gross et al., 1999). Early studies showed increases in racing times when EIPH was diagnosed and a subsequent improvement of racing times upon administration of furosemide (Soma et al., 1985). Treadmill studies have not consistently shown furosemide-induced changes in maximal O_2 consumption, time to fatigue, or the speed at which fatigue occurred in exercising horses (Hinchcliff et al., 1993). However, in these and later studies, the loss of weight associated with furosemide administration did reduce carbon dioxide production, the respiratory exchange ratio, and plasma lactate. Furosemide-induced gains in performance were reversed by addition of a weight equal to the weight of the volume lost. These results suggest that performance benefits associated with furosemide administration to EIPH horses may be unrelated to reduction in hemorrhage and more related to changes in body weight (Soma and Uboh, 1998). Based on human studies, this interpretation should not be extended to circumstances in which the race distance is long and exertion prolonged. In these cases, the detrimental effects of dehydration would rapidly offset the advantage of running under reduced weight.

A final issue related to use of furosemide in racing animals involves the regulation of administration of furosemide and other drugs to equine athletes. The control of drugs in racing animal is discussed in more detail in Chapter 57. Doses of 250–500 mg furosemide per horse (0.5–1.0 mg/kg) administered IV no later than 4 hours prior to post time are permitted for medication of horses with EIPH in most jurisdictions in the United States. Specific regulations at a given track should be consulted. The regulation of furosemide administration according to track rules has been approached in a variety of ways. Some jurisdictions use a combination of urine specific gravity of 1.015 or 1.010 and a plasma concentration of greater than 60 or 100 ng/ml as an indication of a violation of the rules. The combination of these two parameters, low specific gravity and high plasma concentration, will suggest that an irregularity related to dose, time, or route of furosemide administration occurred (Soma and Uboh, 1998). By considering both urine specific gravity and plasma furosemide concentration, the probability of misclassifying horses as being in violation of regulatory concentrations is reduced (Chu et al., 2001).

Widespread use of furosemide in racing animals also presents problems related to screening of urine for presence of regulated substances. The urinary concentration of coadministered drugs may be diluted as a function of furosemide-enhanced diuresis. Urinary excretion rates of some drugs, especially those that are water-soluble acids, may be altered as a result of furosemide competition for the organic anion tubular secretion pathway. Furosemide has been shown to decrease the urinary concentration of phenylbutazone through both of these mechanisms. In comparison, the excretion rate of other agents, notably fentanyl, procaine, and methylphenidate, is increased by furosemide. Faster clearance of these substances may make it more difficult to detect illegal use prior to a race (Hinchcliff and Muir, 1991).

Other Uses

Furosemide has been shown to decrease pulmonary resistance and increase dynamic compliance in ponies with chronic obstructive pulmonary disease. In this case, the rapidity of the response and the finding that the response could be blocked by NSAIDs suggested a cyclooxygenase-mediated event rather than an effect dependent upon loss of body fluid (Broadstone et al., 1991). Immediate changes in pulmonary pressures in other species (e.g., dogs with pulmonary edema) are thought to be related to direct effects of furosemide on the pulmonary vasculature. Similar to use in small animals, furosemide is indicated for treatment of CHF and associated pulmonary edema by decreasing cardiac preload and plasma volume. Furosemide is also recommended to increase urine flow in acute renal failure in horses.

Inhibitors of Na^+/Cl^- Symport (Thiazide and Thiazide-Like Diuretics)

Chemistry/Formulations

Thiazide diuretics are benzothiadiazines or analogs and are derivatives of CA-inhibiting sulfonamides. Compared to carbonic anhydrase inhibitors which promote the elimination of sodium bicarbonate, thiazides promote renal excretion of sodium chloride producing a true saluretic effect. Two of the first thiazides synthesized, and the two drugs most commonly used in veterinary medicine, are chlorothiazide (Diuril®, human-approved 250 and 500 mg tablets, 50 mg/ml suspension, and 500 mg/vial injectable available) and hydrochlorothiazide (Hydrozide®, veterinary-approved 25 mg/ml injectable; HydroDiuril®, human-approved 25, 50, and 100 mg tablets and 10 mg/ml oral suspension). Both drugs are derivatives of benzothiadiazine and are water soluble. Hydrozide® is the only veterinary-approved product for use in cattle and has a 72-hour milk withholding time for lactating dairy cattle; no meat withholding time has been reported. Newer generation, more lipid-soluble benzothiadiazine derivatives include cyclothiazide and methychlothiazide.

Nonbenzothiadiazine derivatives have thiazide-like effects, and these drugs also promote excretion of sodium with chloride. Quinazolinone derivatives are in this class and include metolazone and chlorthalidone. These drugs are not commonly used in veterinary medicine but are examples of thiazide-like diuretics.

Mechanisms and Sites of Action

The primary site of action of thiazides is the distal convoluted tubule, with some secondary activity, possibly CA-related, in the proximal tubule. In the distal tubule, Na/Cl reabsorption is mediated by an electroneutral cotransport (symport) system (Figure 24.9). The driving force for Cl^- entry is the transmembrane Na^+ gradient established by the activity of basolateral Na^+/K^+-ATPase. The apical (luminal) Na/Cl cotransporter is reversibly inhibited by thiazides. Basolateral movement of Cl^- out of the cell is mediated by a Cl^- channel and K^+ by a K^+ channel. The lumen-negative transepithelial potential generated by the polarity of K^+ and Cl^- exit may drive anion reabsorption via a paracellular shunt pathway. Ca^+ reabsorption is enhanced by thiazides, by increasing distal tubule Na^+/Ca^{2+} exchange (antiporter) on the basolateral membrane due to low intracellular sodium. Because 90% of filtered Na^+ is reabsorbed prior to the distal tubule, the peak diuresis caused by thiazides is moderate compared to loop diuretics. Like loop diuretics, thiazides enhance excretion of K^+ by increasing the delivery of Na^+ to the distal tubule.

Absorption and Elimination

Thiazide and thiazide-like diuretics are absorbed slowly and incompletely from the gastrointestinal tract. Most drugs in this class are highly protein bound and undergo renal excretion (chlorothiazide and hydrochlorothiazide) or by a combination of renal and biliary routes (thiazide-like drugs). Hydrochlorothiazide is less protein bound (40%) than others in the class and partitions and accumulates in red blood cells (Velazquez et al., 1995). All drugs in this class gain access to the lumen of the renal tubule via an organic acid secretory pathway. Hence effectiveness of these drugs is decreased if renal blood flow diminishes.

Toxicity, Adverse Effects, Contraindications, and Drug Interactions

Similar to loop diuretics, most problems associated with administration of thiazides are related to fluid and electrolyte disturbances. Potassium wasting, especially with concurrent use of digitalis, increases the risk of cardiac arrhythmias. Low K^+ may secondarily affect conversion of proinsulin to insulin, leading to hyperglycemia. Enhanced calcium reabsorption can lead to hypercalcemia, and mild magnesuria may cause magnesium deficiency. Depletion of extracellular volume, hyponatremia, hypochloremia, and hypochloremic metabolic alkalosis may occur as adverse effects with prolonged or aggressive thiazide use. Because thiazides block solute reabsorption at nephron sites involved in dilution of urine, these agents increase the risk of hyponatremia under conditions of increased consumption of hypotonic fluids. CNS and gastrointestinal effects may occur but are not common.

Although thiazides contain sulfur, they do not induce reactions similar to sulfa antimicrobials (Trepanier, 2004). Patients with severe renal disease, hypovolemia, or electrolyte disturbances are poor candidates for thiazide therapy. Impaired hepatic function that may be worsened by volume contraction (leading to hepatic encephalopathy) is a contraindication for thiazide use. Diabetic patients are at risk for thiazide-induced derangements of glucose and insulin.

Drug interactions may include decreased effects of anticoagulants and insulin and increased effects of some anesthetics, diazoxide, digitalis glycosides, lithium, loop diuretics, and vitamin D. Combination therapy using low-dose thiazides with antihypertensives (e.g., ACE inhibitors) is currently considered to be an effective alternative strategy for management of human hypertension (Neutel et al., 1996). At low doses, adverse effects of thiazides are decreased, making their use in combination regimens particularly appealing.

Thiazides are reported to prolong the half-life of quinidine. In the face of thiazide-induced hypokalemia, an elevated plasma quinidine level increases the risk of polymorphic ventricular tachycardia (torsades de pointes), a condition that can deteriorate into ventricular fibrillation (Jackson, 1996). NSAIDs may reduce the effectiveness of thiazides and loop diuretics (Brater, 1998).

Therapeutic Uses

Thiazides may be used to treat edema of cardiac, hepatic, or renal origin. Typical oral dosages in the dog and cat are 20–40 mg/kg every 12 hours (chlorothiazide) and 2–4 mg/kg every 12 hours (hydrochlorothiazide). Effects of both chlorothiazide and hydrochlorothiazide peak at 4 hours and last up to 12 hours, with hydrochlorothiazide typically having a longer duration (12 hours) than chlorothiazide (6–12 hours). Cattle may be treated for udder edema with hydrochlorothiazide (125–250 mg IV or IM once or twice daily). Oral chlorothiazide (not a veterinary-approved product) at a dose of 4–8 mg/kg once or twice daily has been substituted for injectable hydrochlorothiazide following the first or second day of parenteral treatment.

Thiazides have previously been used in veterinary medicine in management of the early stages of CHF. As mentioned previously, early use of loop and thiazide diuretics in CHF activates aldosterone-mediated mechanisms that eventually lead to cardiac deterioration. For this and other reasons, the use of thiazides in treatment of CHF is not common in veterinary medicine. In general, furosemide is more commonly used in veterinary medicine to treat edema, whether it be cardiac, hepatic, or renal in origin. In human medicine, thiazides are commonly used in the management of hypertension. Because thiazides increase reabsorption of calcium, they may also be beneficial in treatment of calcium nephrolithiasis in humans and animals.

Thiazides are used effectively to reduce the volume of urine in patients with nephrogenic diabetes insipidus. Diuretic-induced volume contraction leads to increased proximal tubule reabsorption and a decrease in urine volume of 30–50%. Although dosages are individualized in these patients, starting ranges of 10–20 mg/kg twice daily (chlorothiazide) or 2.75–5.5 mg/kg (hydrochlorothiazide) twice daily have been suggested (Nichols and Thompson, 1995).

Inhibitors of Renal Epithelial Sodium Channels (K^+-Sparing Diuretics)

Chemistry/Formulations

The two relevant drugs in this class, triamterene (Dyrenium®) and amiloride (Midamor®), both belong to the class of cyclic amidine diuretics. Triamterene is a pteridine ring with amino groups at the 2, 4, and 7 positions. It was originally synthesized as a folic acid antagonist. Amiloride consists of a substituted pyrazine ring with a carbonylguanidinium side chain. A number of analogs of this basic structure have been synthesized and have been useful tools in elucidating mechanisms of sodium transport. Both triamterene and amiloride are organic bases and are secreted into the proximal tubule by an organic base transport system. Although neither of these drugs is used with frequency in veterinary medicine, triamterene is the more commonly used and hence will be the focus of these discussions. No parenteral forms of the drug are available; oral preparations are available in 50 and 100 mg capsules.

Mechanisms and Sites of Action

Triamterene and amiloride cause a mild increase in excretion of NaCl and a retention of K^+. Both drugs slightly augment diuresis and are used in combination with loop diuretics or thiazides to decrease K^+ excretion (hence the term K^+-sparing). Both drugs act at the late distal tubule (or connecting tubule) and collecting duct to block the electrogenic transport of Na^+. As with other diuretics, the basolateral Na^+/K^+-ATPase creates an electrochemical gradient that drives events at the luminal surface of the tubular cell. In this case, the principal cells of the connecting tubule contain a Na^+ channel in their luminal membrane that provides a pathway for entry of Na^+ and sets up a lumen-negative transepithelial potential. The transepithelial voltage is the key force involved in driving K^+ out of the principal cell and into the tubular lumen. Blockade of Na^+ channels by triamterene or amiloride hyperpolarizes the luminal membrane, reduces the lumen–negative potential difference, and decreases the excretion of K^+, H^+, Ca^{2+}, and Mg^{2+}. It has been speculated that effects of both of these drugs may also be mediated by inhibition of a Na^+/H^+ antiport located in the late distal tubule and collecting duct. Additional, direct effects on Mg^{2+} excretion may also occur.

Triamterene has been shown to exert cardiac effects that are not secondary to alterations in renal function. Early studies documented a prolongation of the cardiac action potential duration and functional refractory period and an increase in myocardial contractile force. Triamterene has also been shown to decrease digitalis-induced K^+ loss from the heart and increase the dose of digitalis necessary to induce toxic effects in dogs (Palmer and Kleyman, 1995; Netzer et al., 1995). Neither triamterene nor amiloride has been shown to affect renal hemodynamics or glomerular filtration rates, and neither acts as an aldosterone antagonist.

Absorption and Elimination

Both amiloride and triamterene are administered orally; triamterene is up to 70% bioavailable, but neither drug has been extensively evaluated in most veterinary species. Amiloride is renally excreted. The pharmacokinetics of triamterene are complex. The parent drug is converted in the liver to an active metabolite, 4-hydroxytriamterene sulfate, which is actively secreted into the renal tubules. Hence renal or hepatic disease could impair elimination of triamterene. The peak onset of action of triamterene is 6–8 hours, with effects persisting up to 12–16 hours.

Toxicity, Adverse Effects, Contraindications, and Drug Interactions

The most important potential adverse effect of these drugs is hyperkalemia. The presence of diseases or circumstances that may increase the risk of hyperkalemia (e.g., renal failure, coadministration of other drugs with K^+-sparing properties, including ACE inhibitors and K^+ supplements and NSAIDs) should be noted and these patients treated with other diuretic combinations. Triamterene may decrease GFR and, in combination with NSAIDs, has been shown to increase the likelihood of hyperkalemia and renal dysfunction. Triamterene-induced renal casts may be responsible for increased risk of interstitial nephritis and renal stones. Both triamterene and amiloride may induce hypersensitivity reactions that include rash and photosensitivity in humans. CNS, gastrointestinal, and hematological side effects have also been reported. As with most other diuretics, use in patients with severe hepatic disease or renal disease is contraindicated. In human patients with hepatic disease, the mild folic acid antagonism inherent in triamterene may increase the risk of megaloblastosis.

Therapeutic Use

Because these drugs have relatively weak diuretic properties, they are clinically important primarily because of their K^+-sparing properties in combination with loop and thiazide diuretics. Both have been used in this capacity for treatment of edema associated with CHF, liver cirrhosis, nephrotic syndrome, steroid-induced edema, and idiopathic edema. Triamterene is administered at a dose of 2–4 mg/kg/day orally to dogs with food to avoid gastrointestinal side effects.

Antagonists of Mineralocorticoid Receptors (Aldosterone Antagonists and K^+-Sparing Diuretics)

Chemistry/Formulations

Spironolactone is a 17-spirolactone and along with eplerenone are the only aldosterone antagonists approved in the United States. Canrenone, an active metabolite of spironolactone, and potassium canrenoate are closely related structurally and are available in other countries. All of these drugs share a four-ring, steroid structure similar to the mineralocorticoid aldosterone. Spironolactone is available as a human-approved oral preparation (Aldactone®) in 25, 50, and 100 mg tablets and eplerenone is available in 25 and 50 mg tablets.

Mechanisms and Sites of Action

Aldosterone is a steroid hormone that binds to mineralocorticoid receptors (MRs) located in the cytoplasm of target cells. The inactive MR complex is bound to heat shock protein 90 (HSP90), a protective chaperon protein, and is incapable of binding to target DNA sequences. Upon binding of aldosterone, HSP90 dissociates from the receptor–hormone complex, allowing movement of the activated receptor into the nucleus. The complex binds to target sequences of DNA referred to as mineralocorticoid-response elements (also termed hormone-responsive elements) that regulate transcription of downstream, mineralocorticoid-responsive genes. Protein products of these responsive genes, aldosterone-induced proteins (AIPs), cause Na^+ reabsorption and increase excretion of K^+ and H^+ in the late distal tubule and collecting duct. AIPs are thought to have multiple effects, including activation, redistribution, and de novo synthesis of Na^+ channels and Na^+/K^+-ATPase, changes in permeability of tight junctions, and increased mitochondrial production of ATP. These effects combine to cause an increase in Na^+ conductance of the luminal membrane and increased Na^+ pump activity in the basolateral membrane. As a result, Na and Cl transport is increased across tubular epithelial cells, and the lumen-negative transepithelial voltage is increased. Secretion of K^+ and H^+ into the tubular lumen increases with increasing voltages.

Aldosterone antagonists act by binding to the MR and facilitating the release of HSP90 from the steroid-binding subunit of the receptor. The unprotected MR complex is thought to be inactivated by proteases. In the absence of activated MRs, gene transcription is not induced, AIPs are not produced, and the physiological effects of aldosterone are blocked.

In addition to antagonism of aldosterone, spironolactone is thought to act in a manner similar to calcium channel blockers to cause direct vasodilation. By binding to plasma membrane sites, spironolactone may inhibit inward slow calcium channels and depress contractions dependent on release of calcium from the sarcoplasmic reticulum. Aldosterone antagonists have also been shown to increase nitric oxide vasodilation and circulating levels of atrial natriuretic peptide as evaluated in the dog. Spironolactone may produce antiarrhythmic effects by blocking the ether-a-go-go protein on the cardiac potassium ion channels (Gómez et al., 2005). Hence direct and aldosterone-mediated effects of the drug may contribute to its usefulness in treatment of cardiac disease (Endou and Hosoyamada, 1995).

Absorption and Elimination

In humans, spironolactone is absorbed moderately well (60–90%), is highly protein-bound, and is extensively biotransformed in the liver, exhibiting a first-pass effect. An active metabolite, canrenone, has a longer half-life than the parent drug and extends the biological effects of spironolactone to about 16 hours in humans. Spironolactone has approximately 60% oral bioavailability in dogs (Karim et al., 1976) and exhibits near proportional drug exposure (canrenone) from 0.7 to 8 mg/kg PO (Guyonnet et al., 2010). Peak diuresis occurs as late as 2–3 days after initiation of therapy. Aldosterone antagonists do not require secretion into the renal tubule to induce diuresis. Greater effects of aldosterone antagonists are expected as the concentration of aldosterone increases and conversely if low concentrations of aldosterone are present, less effects are expected.

Toxicity, Adverse Effects, Contraindications, and Drug Interactions

Hyperkalemia, dehydration, and hyponatremia are the most common side effects of aldosterone antagonists. When used alone, these drugs can also cause hyperchloremic metabolic acidosis. In humans, sexual side effects limit the use of spironolactone in some patients due to effects on progesterone and androgen receptors. This lack of receptor specificity drives continued efforts to identify a more-MR-specific antagonist for use in human medicine.

As previously noted, combination of any K^+-sparing diuretic, including spironolactone, with ACE inhibitors must be accomplished cautiously to avoid hyperkalemia. This is a clinically significant scenario that merits patient monitoring of plasma K^+ concentrations. Spironolactone may decrease oral bioavailability of digoxin due to increased p-glycoprotein expression (Ghanem et al., 2006), but may decrease digoxin renal clearance; therefore, therapeutic drug monitoring of digoxin is recommended when administered concurrently with spironolactone (O'Brien et al., 1985). The presence of spironolactone in plasma may also confound therapeutic drug monitoring of digoxin if a cross-reactive antidigoxin antibody is used in the assay. Aspirin apparently blocks spironolactone-induced natriuresis (Endou and Hosoyamada, 1995).

Therapeutic Uses

The effectiveness of aldosterone antagonists in promoting diuresis is largely dependent upon elevated concentrations of endogenous aldosterone. Aldosterone secretion increases upon activation of the renin–angiotensin–aldosterone system, which, in turn, responds to reductions in serum sodium, effective blood volume, and cardiac output, and decreases in serum K^+. Secondary hyperaldosteronism and edema are associated with cardiac failure, hepatic cirrhosis, nephrotic syndrome, and severe ascites. Spironolactone is used in veterinary medicine at a dose of 2–4 mg/kg/day orally in management of refractory edema associated with these conditions and has been used in the management of hepatic cirrhosis. In both human and veterinary medicine, aldosterone antagonists are commonly administered with a thiazide or loop diuretic to increase peak diuresis and to spare K^+.

Elevated aldosterone levels have been shown to be a useful prognostic indicator in heart failure, with higher levels correlated with a poorer prognosis. Activation of the renin–angiotensin–aldosterone system in arterial hypertension is thought to lead to remodeling of the myocardial collagen network with progressive cardiac interstitial fibrosis. As fibrosis increases, diastolic function deteriorates and pathological cardiac hypertrophy occurs. When aldosterone-mediated effects are blocked by spironolactone, progression of myocardial failure is presumably slowed. A clinical study in humans supported this contention by showing significant delays in progression of CHF in patients treated with spironolactone (Pitt et al., 1999). No comprehensive study has been published to verify this effect in veterinary patients. Diuretic efficacy of spironolactone was not demonstrated in a study combining the drug with furosemide in greyhound dogs (Riordan and Estrada, 2005).

A newer drug, eplerenone, reduced mortality in a human study of heart failure due to myocardial infarction (Weir and McMurray, 2005), and the drug has also been shown to have cardioprotective effects in animal models of myocardial failure (McMahon, 2003). Despite the potential side effect of hyperkalemia associated with coadministration of aldosterone-antagonists and ACE inhibitors, this combination with appropriate dosages has been deemed effective in management of CHF. Addition of furosemide, which enhances elimination of K^+, may decrease the risk of hyperkalemia. Patient monitoring for K^+ derangements is critical to safe implementation of this approach. In veterinary medicine, spironolactone may be useful in patients with CHF secondary to chronic valvular heart disease or dilated cardiomyopathy that become unresponsive to therapy with ACE inhibitors, digoxin, and furosemide.

Methylxanthines

Overview

Methylxanthines (aminophylline and theophylline) are primarily used for bronchodilator effects and are discussed in more detail in Chapter 48. Methylxanthines are adenosine receptor antagonists at lower dosages and higher dosage produce phosphodiesterase inhibitor effects. They produce weak diuresis and natriuresis. The mechanism of diuresis appears in part due to vasodilation of the renal afferent arterial increasing glomerular filtration rate. However adenosine receptors in the proximal convoluted tubule stimulate fluid and bicarbonate transport as well as Na^+/glucose and Na^+/phosphate symport (Rieg et al., 2005). Although not a primary choice as a diuretic, low-dose aminophylline has demonstrated efficacy as an adjunct in human pediatric patients that are refractory to furosemide diuresis (2005; 2012). The clinical utility in veterinary medicine has not been reported, but use of aminophylline as a diuretic adjunct in furosemide-resistant patients is an area that requires further research prior to recommended use in animals.

New and Experimental Agents

Aquaretics

Vasopressin (or arginine vasopressin, AVP) regulates water and solute excretion in the kidney by binding to V2 receptors in the principal cells of the renal collecting duct system. As one of three G-protein-coupled AVP receptor subtypes (V1a, V1b, V2), V2 receptors mediate the antidiuretic effects of AVP. V2 receptor antagonists, so-called aquaretic agents, promote solute-free water excretion. These antagonists hold considerable promise for treatment of edematous states associated with heart failure, liver cirrhosis, nephrotic syndrome, and syndrome of inappropriate secretion of antidiuretic hormone (Verbalis, 2006). While peptide derivatives of AVP have been found to have intrinsic antidiuretic properties, several nonpeptide antagonists are currently approved, including conivaptan and tolvaptan. These drugs typically increase urine volume and decrease urine osmolality and body weight without affecting urinary sodium excretion (Orita and Nakahama, 1998; Serradeil-Le Gal, 1998; Palm et al., 2006). Tolvaptan administered to healthy dogs dose dependently (0.3–10 mg/kg PO) increased urine volume and decreased urine osmolality, without increasing urinary sodium excretion (Miyazaki et al., 2007). Similar effects were observed in dogs with experimentally induced heart failure. In the healthy and CHF-induced experimental dogs, tolvaptan did not increase sympathetic or renin–angiotensin–aldosterone systems, but did increase AVP concentrations. No effects were observed on glomerular filtration rates, renal blood flow, or peripheral vascular resistance. No published clinical trials of tolvaptan in naturally occurring cardiac disease in dogs or cats are available. Conivaptan was shown to improve impaired cardiovascular parameters induced by intravenous infusion of AVP in a dog model, suggesting possible clinical usefulness (Yatsu et al., 2002).

Although vasopressin antagonists represent a promising area of drug development for induction of aquaresis, drugs that interfere with secretion of AVP from the neurohypophysis and drugs that directly inhibit water channels in the collecting ducts are also of interest. Aquaporin-CD, the water channel of the principal cell of the cortical and medullary collecting duct, has been cloned and provides an attractive site for drugs intended to inhibit diuresis.

Neutral Endopeptidase Inhibitors

Neutral endopeptidase (NEP) is an enzyme that rapidly degrades atrial natriuretic factor, the cardiac peptide hormone that increases sodium and water excretion, inhibits the renin–angiotensin–aldosterone system, and produces vasodilation. NEP inhibitors have been investigated for their possible usefulness in increasing circulating concentrations of atrial natriuretic factor and therefore increasing the fractional excretion of sodium. An experimental NEP inhibitor, ecadotril, has been investigated in induced heart failure in dogs (Solter et al., 2000; Mishima et al., 2002) and been shown to attenuate progression of disease. NEP inhibitors have been shown in dogs to enhance the actions of furosemide and prevent the furosemide-induced activation of the renin–angiotensin–aldosterone system (Kittleson and Kienle, 2007).

Dopamine Receptor Agonists

Dopaminergic receptor 1 (DA_1) and dopaminergic receptor 2 (DA_2) have both been considered targets for low–dose dopamine therapy of low output renal failure in dogs and humans. Efficacy of low-dose dopamine has been questioned and concerns have been raised over renal morbidity and gastrointestinal side effects. It has been noted that although dopamine increases renal perfusion and urine output, increases in creatinine clearance are not sufficient to achieve therapeutic efficacy in management of renal failure. In comparison, DA_1 selective agonists may be more effective at increasing renal blood flow, inducing diuresis and natriuresis, and increasing glomerular filtration rate. This is particularly true in cats, a species that does not respond well to the renal effects of dopamine. Fenoldopam, a selective DA_1 agonist, has been investigated in both dogs and cats. In cats, fenoldopam at a dose of 0.5 μg/kg/min induced diuresis in a delayed manner, by 6 hours postadministration, increased urine output, sodium excretion, fractional clearance of sodium, and elimination of creatinine (Simmons et al., 2006).

Angiotensin Converting Enzyme Inhibitors and Angiotensin Receptor Antagonists

Chemistry/Formulations

Numerous angiotensin converting enzyme (ACE) inhibitors are approved for use in humans and animals. Captopril was the first ACE inhibitor marketed and is available in oral dosage from 12.5 to 100 mg tablets and in combination with hydrochlorothiazide. Enalapril maleate is a prodrug ester approved for use in dogs and in humans and is available in tablets ranging from 1 to 20 mg and as a 1 mg/mL oral solution. Enalaprilat is the active drug and is available as an injection (1.25 mg/mL), but rarely used in veterinary medicine. Benazepril hydrochloride is available as 5–40 mg tablets and is approved in some countries for use in dogs and cats. Imidapril and ramipril are also approved for use in some countries for dogs. Although numerous other ACE inhibitors are available, they are less commonly used.

Angiotensin receptor antagonists, also known as angiotensin receptor blockers (ARBs) are approved for use in humans. Losartan, telmisartan, valsartan, and irbesartan, available for oral administration, have rarely been used in dogs and cats, but may see increasing use in veterinary medicine.

Mechanisms and Sites of Action

The action of ACE inhibitors is to decrease the metabolism of angiotensin I (ATI) to angiotensin II (ATII), which produces profound physiological effects, as described in Section Renin–Angiotensin–Aldosterone System (Figure 24.10). ACE also inactivates bradykinin, therefore ACE inhibitors increase bradykinin and subsequently prostaglandins both of which may provide additional benefits. The efficacy of the different ACE inhibitors are similar in humans, but differences in pharmacokinetics and individual sensitivity to adverse effects are the primary differences for ACE inhibitor selection for specific patients.

Angiotensin receptor blockers are selective antagonists of the angiotensin receptor type 1 (AT_1). Although they are considered reversible antagonists, their (or their active metabolite) antagonism cannot be overcome with higher concentrations of ATII. The ARBs are specific for inhibiting ATII in contrast to ACE inhibitors that can additional effects such as decreased bradykinin metabolism.

The ACE inhibitors decrease ATII formation while the ARBs directly inhibit ATII binding to AT receptors, decreasing ATII effects including direct vasoconstriction, rapid and slow pressor responses, vasopressin and aldosterone release, sympathetic nervous system tone, enhanced release of norepinephrine, and adrenal catecholamine release. Although ACE inhibitors and ARBs are expected to have minimal blood pressure effects in healthy animals, animals with high concentrations of renin and ATII can have profound effects. In humans, ACE inhibitors and ARBs are usually started at a low dose and increased over time to minimize acute hypotension. However, hypotension is much less of a problem in dogs and cats as, in general, the ACE inhibitors and ARBs are relatively low-efficacy vasodilatory drugs.

Absorption and Elimination

Most ACE inhibitors are formulated as a prodrugs to enhance oral bioavailability. The exception is captopril, which is an active drug. The oral bioavailability of most ACE inhibitors in dogs and cats are low, but sufficient for clinically relevant effects. In contrast, the oral bioavailability of enalapril in horses is very low and enalapril is not an effective PO drug in horses (Gardner et al., 2004). Additionally, when benazepril, ramipril, quinapril, and perindopril were administered PO to horses only benazepril produced reasonable effects in horses (Afonso et al., 2013). The oral bioavailability of enalapril and benazepril are not affected by feeding, but the oral bioavailability of captopril, imidapril, and ramipril are decreased by administration with food. Enalapril, benazepril, imidapril, and ramipril are prodrugs metabolized to the active metabolites enalaprilat, benazeprilat, imidaprilat, and ramiprilat. Enalaprilat and captopril are primarily eliminated unchanged in the urine while benazeprilat, ramiprilat, and imidaprilat are approximately equally eliminated in the urine and bile. Therefore animals with decreased renal function will have decreased elimination of captopril and enalaprilat, which could lead to exaggerated and adverse effects if dosages are not adjusted. Thus benazepril, ramipril, and imiapril are preferred in animals with decreased renal function. The doses of ACE inhibitors are: enalapril 0.25–0.5 mg/kg PO q 12–24 h; benazepril 0.25–0.5 mg/kg PO q 12–24 h; imidapril 0.25 mg/kg PO q 24 h; and ramipril 0.125–0.25 mg/kg PO q 24 h.

The pharmacokinetics of the oral ARBs losartan, telmisartan, valsartan, and irbesartan have been reported in dogs, but not in cats (Huang et al., 2005; Baek et al., 2013). In cats, telmisartan produced greater and longer lasting effects than losartan and irbesartan. However, limited dosage ranges were assessed and the pharmacokinetics, including oral bioavailability and half-life, are unknown; therefore, it is unclear if telmisartan is a better choice in cats or if the dosages of losartan and irbesartan were inappropriate (Jenkins et ., 2015). The oral bioavailability of losartan in dogs is relatively low, 23–33%, but the absolute oral bioavailability of the other ARBs have not been reported (Christ et ., 1994). In humans, the oral bioavailability of most ARBs is <50%. In humans, losartan is metabolized to an active metabolite, E-3174, which is more potent than losartan, but minimal amounts of the metabolite are produced in dogs (Suzuki et al., 2001). Metabolism of losartan has not been reported in cats. Despite the lack of the active metabolite in dogs, effects of losartan against exogenous ATII were profound, but of short duration. In humans, ARBs are primarily eliminated by hepatic metabolism and biliary secretion with changes in renal function having minimal effects on their pharmacokinetics. Food markedly decreases the oral absorption of telmisartan and valsartan but not losartan and irbesartan in humans. The effect of food on the pharmacokinetics of ARBs in dogs has not been extensively evaluated, therefore it would be prudent to administer to fasted animals until further data are available.

Toxicity, Adverse Effects, Contraindications, and Drug Interactions

Angiotensin converting enzyme inhibitors in dogs are cats are, overall, well tolerated. Acute renal failure is an adverse effect with ACE inhibitors and ARBs that warrant close monitoring. Renal adverse effects may be more severe and rapidly progressive in animals treated with enalapril or captopril as drug accumulation occurs once renal dysfunction starts, but renal adverse effects can occur with any ACE inhibitor. Renal failure risks are increased in animals with renal hypotension as ATII vasoconstriction of the efferent arteriole maintains renal blood pressure, but is blocked by ACE inhibitors and ARBs. In contrast, animals with renal hypertension and proteinuria can have therapeutic benefits of ACE inhibitors and ARBs. Animals that are dehydrated and hyponatremic are at higher risk for renal failure. Serum creatinine should be routinely monitored for development or worsening of azotemia, initially within a week of initiating therapy and then periodically throughout therapy. If azotemia is detected, decreasing the dose of concurrent diuretics (decreasing dehydration and hyponatremia) may be appropriate in addition to decreasing or discontinuing ACE inhibitor or ARB therapy.

Hyperkalemia due to ACE inhibitors and ARBs in animals is rare unless combined with potassium-sparing diuretics or renal failure. The RAAS is important for the development of normal kidney anatomy in utero and exposure to ACE inhibitors and ARBs result in numerous birth defects and should be avoided in pregnant animals and neonates. Although hypotension can occur with ACE inhibitors and ARBs, it is uncommon in animals unless the animal is dehydrated or receiving other vasodilators. In humans, coughing and angioedema is a common adverse effect due to enhanced bradykinin from ACE inhibitors, but not ARBs; however, coughing and angioedema are rarely or not reported adverse effect in animals.

There is the potential for drug interactions with ACE inhibitors and ARBs in dogs and cats. The risk of renal adverse effects appears to increase and the antihypertensive effects diminished when combined with NSAIDs that affect prostaglandin formation (KuKanich et al., 2012). Concurrent administration of vasodilators with ACE inhibitors are expected to produce exaggerated vasodilatory effects, which could result in systemic hypotension in addition to renal hypotension, increasing the risk of renal toxicity. The concurrent use of diuretics can lead to hyponatremia and dehydration, which increases the risk of renal toxicity. Likewise, the concurrent use of nephrotoxic drugs, including but not limited to aminoglycosides, amphotericin B, and cisplatin, increases the risk of renal toxicity. Combination of ACE inhibitors with potassium sparing diuretics, including spironolactone, increases the risk of hyperkalemia. In humans, ACE inhibitors decrease the clearance of digoxin, but this interaction has not been reported in animals.

Therapeutic Uses

Angiotensin converting enzyme inhibitors are commonly administered to dogs with chronic heart disease. Although ACE inhibitors are used in cats with hypertrophic cardiomyopathy, there are less data available demonstrating therapeutic benefits. However, numerous laboratory studies and clinical trials are available in dogs demonstrating the benefit of ACE inhibitors in dogs with chronic heart disease (dilated cardiomyopathy and chronic valvular diseases) often combined with other therapeutics, including diuretics (primarily furosemide and spironolactone), digoxin, and pimobendan (Chapter 21), as appropriate (Lefebvre et al., 2007). The most important clinical effects for clients are improved quality of life and increased survival times when affected dogs with symptomatic heart disease are treated with ACE inhibitors in combination with appropriate concurrent therapeutics. Dogs treated chronically had greater decreases in pulmonary edema, respiratory effort and coughing, and improved appetite, exercise tolerance/ mobility/ activity, attitude, and general demeanor with the addition of ACE inhibitors. Despite the clinical improvement, specific physiological measurements such as cardiac output, stroke volume, pulmonary arterial pressures, and systemic vascular resistant are often unaffected. The data are more equivocal with dogs exhibiting asymptomatic/ subclinical heart disease and routine use of ACE inhibitors in these dogs are not currently recommended. There are no studies reporting the efficacy of ARBs in dogs or cats with naturally occurring chronic heart disease, but the availability of cost-effective ARBs will likely increase their use in veterinary medicine.

ACE inhibitors are also administered to dogs and cats for the treatment of proteinuria and glomerular diseases (Brown et al., 2013; King et al., 2006). Dogs with a urine protein to creatinine ratio (UPC) exceeding 0.5 are recommended to be treated with an ACE inhibitor. Clinical trials have demonstrated efficacy of enalapril in decreasing proteinuria in dogs with glomerular disease and delayed the onset of azotemia (Brown et al., 2013). Although studies demonstrating the efficacy of benazepril on dogs with proteinuria are lacking, benazepril is often administered to dogs with elevated UPC and glomerular disease. An advantage of benazepril is that its pharmacokinetics are minimally affected by renal dysfunction, compared to enalapril which is significantly altered. There are no reports of ARBs used for the management of naturally occurring proteinuria and glomerular disease in dogs, but with the availability of cost-effective ARBs they will likely be used more commonly. In cats, benazepril has been recommended for the management of chronic kidney disease (CKD) with elevated UPC (King et al., 2006). Benazepril significantly decreased UPC and maintained plasma protein concentrations compared to placebo in cats. However, there was no significant difference in survival time and need for parenteral fluids/ euthanasia/ death due to renal failure, but there was large variability. Similarly, telmisartan significantly decreased UPC in cats with CKD (Sent et al., 2015).

ACE inhibitors as a sole treatment for hypertension in dogs and cats have a low efficacy and most often do not provide a clinically desired effect. Vasodilators such as amlodipine (Chapter 21) are often administered concurrently with ACE inhibitors to achieve clinically desired decreases in blood pressure.

Section 7

Drugs Acting on Blood and Blood Elements

25

Anticoagulant, Antiplatelet, and Hemostatic Drugs

Mark G. Papich

There are only a small number of drugs used in veterinary medicine to affect the coagulation system. Although important coagulopathies have been identified in animals, and thromboembolism is an important component of several diseases, we lack well-controlled studies to identify the best drug to manage these problems. We often use drugs that are approved for humans to manage thromboembolic diseases but the doses and frequency of administration of these drugs in animals often is undetermined and we extrapolate doses from human medicine, or use anecdotal information to base therapy. For example, there is not a clear understanding for the most effective antiplatelet dose of aspirin to administer to dogs and cats, or whether it is even effective. Likewise, although heparin is an important anticoagulant – including the low-molecular-weight forms – the optimum dose is unclear.

The conventional thinking regarding the use of anticoagulant and antiplatelet drugs is that coagulation disorders arise either on the arterial side or the venous side of the circulation. Disorders of high shear force and arterial injury induce platelets to become activated and induce a hypercoagulable state. The resulting clot is platelet rich, with platelets embedded in fibrin (the so-called *white thrombi*). Coagulation disorders arising on the venous side are often attributed to slow or sluggish blood and blood pooling. These clotting disorders are composed predominantly of trapped red blood cells embedded in fibrin (the so-called *red thrombi*). These clots can produce pulmonary thromboembolism. Therefore, treatment of clotting disorders on the venous side traditionally employ anticoagulant drugs and clotting disorders on the arterial side employ antiplatelet drugs. Obviously, the clotting disorders cannot so easily be divided into these two categories and for some diseases both components are important. For example, one of the most serious diseases for which thromboembolism plays a role is heart disease in which blood may pool in the atrium and send emboli to the pulmonary circulation, resulting in pulmonary thromboembolism. These occur in the pulmonary arteries and both antiplatelet and anticoagulant drugs have been used to prevent these problems. Dogs with immune-mediated hemolytic anemia (IMHA) have generalized thromboembolic disease of both veins and arteries and pulmonary thromboembolism (PTE) is a common complication (Kidd and Mackman, 2013). Dogs with IMHA may be at more risk because some of the drugs used to treat this disease, such as glucocorticoids and cyclosporine, may increase platelet activity (Thomason et al., 2016; Kidd and Mackman, 2013)., Evidence-based recommendations for other diseases in which thromboembolism plays a role in dogs and cats are found in the review by Lunsford and Mackin (2007).

Drugs such as heparin and coumarin inhibit hemostasis by impeding clot formation. Both are used for treatment and prevention of thromboembolic disorders in animals. Newer anticoagulants – factor Xa inhibitors (rivaroxaban, apixaban) and thrombin inhibitors (dabigatran) – are becoming more popular in human medicine but their use in animals is still rare. Antiplatelet drugs in veterinary medicine are limited to aspirin and clopidogrel. We have good evidence for effectiveness of clopidogrel, but the value of aspirin as an antiplatelet agent is being questioned. There are also hemostatic agents – those intended to increase blood clotting, or fibrin formation – but these have little use in clinical veterinary medicine and will be covered only briefly in this chapter.

Hemostasis

Hemostasis refers to prevention or control of hemorrhage. Physiological control systems operate to ensure fluidity of blood under normal conditions, yet opposing systems promote coagulation when the circulatory system is invaded (Edelberg et al., 2001). Hemostasis is achieved through a series of interdependent mechanisms, including vascular spasm of the injured artery or

vein, local aggregation of platelets into a plug, coagulation of the blood into a clot, and subsequent dissolution of the formed clot by fibrinolysis (Figure 25.1 and Figure 25.2). The basic process of hemostasis can be separated into the vascular, platelet, coagulation, and fibrinolysis phases. The phases overlap considerably, and events in one step promote and even cause development of subsequent phases.

Vascular and Platelet Phases

The vascular and platelet phases are closely allied, with the vascular endothelium having a multitude of both anticoagulant and procoagulant functions. Ordinarily, platelets circulate in an inactive state. Nitric oxide (NO) and prostacyclin (PGI_2) released by vascular endothelial cells help to maintain the inactive state of platelets. Reduced levels of NO may contribute to thromboembolic disease in some animals. The endothelial cells also produce ADPase, that helps to degrade adenosine diphosphate (ADP). Adenosine diphosphate is a potent stimulator of platelet activation. Immediately after a blood vessel is injured and the subendothelium exposed, tissue factor (TF) and von Willebrand factor (vWF) are exposed, which attracts platelets to the injured endothelium. Platelets have specialized receptors for vWF and TF that facilitate this attraction to the endothelium. For platelets to properly attach to a traumatized area, vWF must be present because the platelets express a vWF integrin receptor that facilitates adherence. Animals deficient in vWF may have bleeding disorders that may be treated by medications that stimulate vWF. Agents such as desmopressin acetate (discussed in Section Desmopressin Acetate) are used for this role. Activation of platelets, in turn, initiates the coagulation factor cascade (Figure 25.1). Once adhesion has occurred, the platelets undergo a change in shape and release diverse substances that recruit further platelets to the clot and further promote the coagulation cascade. The substances involved in activation include ADP, adenosine triphosphate (ATP), serotonin (5-HT), platelet factor 3 and 4, thromboxane A_2 (TXA_2), and platelet-derived growth factor. This aggregation yields a rather loosely formed plug or platelet thrombus at the injury site. The smooth muscle of the vascular wall contracts and platelets adhere to the injured site (Figure 25.2). The local vasoconstrictor response, or

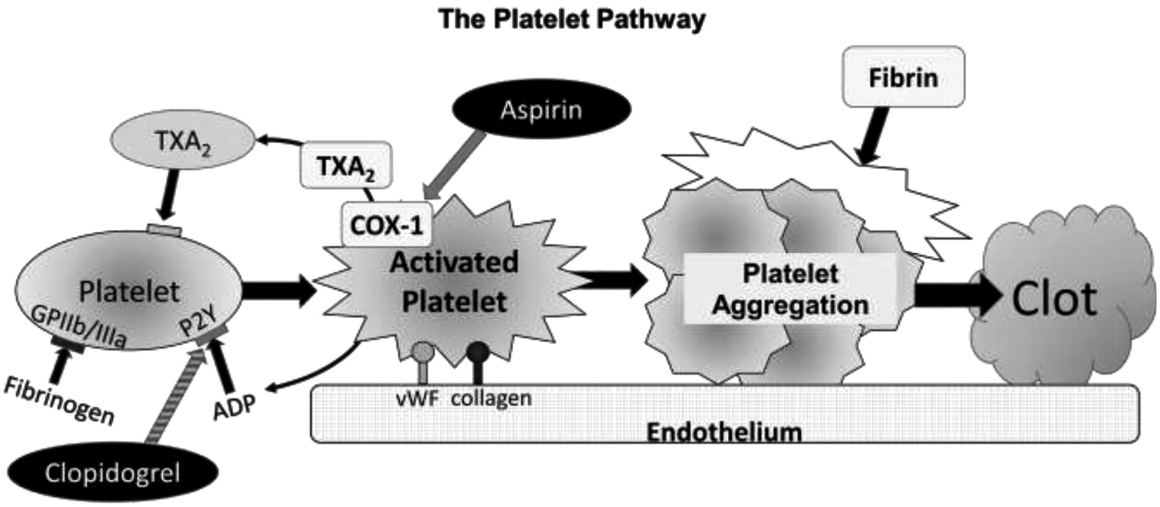

Figure 25.2 The sequence of events, simplified here, to show how activated platelets lead to platelet incorporation into fibrin clot. Sites of drug action are shown in black ovals. Note that the source of TXA$_2$ and ADP are from activated platelets, in which they amplify platelet aggregation by secreting platelet-activating substances. See text for discussion of drugs in each group. ADP, adenosine diphosphate; COX, cyclooxygenase; TXA, thromboxane.

vascular spasm, mechanically retards the flow of blood escaping from the vessel. Vascular spasm may be partly a local reflex or myogenic response and partly humoral, owing to vasoactive agents released from platelets and nearby endothelial cells. Local vasoconstriction lasts as long as 20–30 minutes, during which the ensuing phases of platelet aggregation and blood coagulation take place.

Involvement of Prostaglandins

Adenosine diphosphate is a potent chemical activator of platelet aggregation, which in turn activates a phospholipase that acts on membrane phospholipid to yield arachidonic acid. The latter is transformed by a platelet cyclooxygenase into short-lived but potent aggregating compounds called cyclic endoperoxides (prostaglandins [PGs] G_2 and H_2). (These compounds are also discussed in Chapter 20.) These endoperoxides are converted by cyclooxygenase-1 (COX-1, platelet thromboxane synthase) to the potent aggregating compound called TXA$_2$ (Figure 25.2). Thus platelet clumping initiates formation of chemical agents that promote further platelet aggregation. In contrast, prostacyclin (PGI$_2$) formed by COX-2 is a PG that inhibits platelet aggregation and acts as a counterbalance to thromboxane. Prostacyclin is formed from arachidonic acid and intermediate cyclic endoperoxides. Prostacyclin synthase (COX-2), the enzyme responsible for transformation of PGI$_2$ from the cyclic endoperoxides, is localized in the vascular endothelium rather than in platelets. Once the platelets adhere and aggregate, the contractile proteins in the platelets contract and the platelet plug becomes more tightly bound and organized by incorporation of fibrin strands formed during coagulation (Figures 25.1 and 25.2).

Coagulation Phase

The clotting cascade is comprised of a sequence of events primarily involving a series of activation of *zymogens.* The zymogens are precursor proteins that are converted to an active protease by cleavage of peptide bonds in the precursor molecule. Once activated, these zymogen coagulation factors activate other factors in a sequence until the final protease, thrombin, is generated (Figure 25.1). The clotting factors are designated by Roman numerals (II, VII, VIII, IX, X, etc.; Table 25.1) and once activated,

Table 25.1 Blood coagulation factors and their common names

Factor	Common name	Drug inhibitor
Factor I	Fibrinogen	
Factor II	Prothrombin	Heparin
Factor III	Tissue thromboplastin	
Factor IV	Calcium	Calcium chelators (e.g., EDTA used in test tubes).
Factor V	Proaccelerin	
Factor VII	Proconvertin; serum prothrombin conversion accelerator	Warfarin
Factor VIII	Antihemophilic factor	
Factor IX	Plasma thromboplastin component; Christmas factor	Warfarin
Factor X	Stuart–Prower factor	Heparin, rivaroxaban
Factor XI	Plasma thromboplastin antecedent	
Factor XII	Hageman factor	
Factor XIII	Fibrin stabilizing factor	

are shown with the "a" subscript (IIa, VIIa, Xa, etc.). Calcium also is important in these reactions. Calcium ions (Ca^{++}), referred to as clotting factor IV (Table 25.1), are required for all coagulation reactions except the first two steps in the intrinsic pathway. This dependency is used in the laboratory; Ca^{++}-complexing agents such as citrate and EDTA are used as in vitro anticoagulants (discussed in Section In Vitro Anticoagulants and Clotting Tests).

Fibrinolysis Phase

A plasma β globulin called plasminogen is bound to fibrin and incorporated into the clot along with other plasma constituents. Fibrinolysis is initiated when plasminogen is activated by local agents to plasmin. Tissue-type plasminogen activator is produced by endothelial cells and fibroblasts and utilizes fibrin as a cofactor in the conversion of plasminogen to plasmin. Plasmin is a proteolytic enzyme that digests the fibrin chains into soluble polypeptides, thereby preventing further fibrin polymerization. Plasmin also digests other substances in the clot and surrounding blood, for example prothrombin, fibrinogen, and clotting factors V, VIII, and XII. Formation of plasmin results in dissolution of the clot and also in hypocoagulability of the blood because of loss of clotting factors. Thus fibrinolysis represents the physiological converse of the coagulation process. It serves as a defense mechanism against overactivity of the coagulation mechanism.

Natural Anticoagulants

Antithrombin (AT, formerly called antithrombin-III) is an endogenous anticoagulant. It is a globulin with a molecular weight of 65,000 and has the ability to inactivate factors Xa, IXa, XIa, and XIIa, and thrombin. The anticoagulant activity of heparin is due to its interaction with AT. When AT binds to heparin it markedly increases the rate of inactivation of factor Xa and thrombin. Antithrombin also is called the heparin cofactor. This enzyme is an important thrombin antagonist, but it additionally inhibits activated forms of factors IX, X, XI, and XII. Antithrombin combines in a stable manner with the enzymatically active binding sites of these factors, thereby preventing their accessibility to subsequent substrates in the clotting cascade.

In Vitro Anticoagulants and Clotting Tests

Two categories of chemicals are used to prevent coagulation of harvested blood: those employed in samples of blood intended for physical or chemical examination and those employed to preserve blood for transfusion. Some of these agents can be used to prevent clotting both in vitro and in vivo (heparin), while others are best used only in vitro because of their toxicity (oxalates).

Typically, blood clots in 4–8 minutes when added to a glass tube (red-top tube). To prevent clotting, anticoagulants may be added for blood sample diagnostic tests. The chelator ethylenediaminetetra acetic acid (EDTA*)* can be added to tubes to chelate calcium and prevent clotting (purple-top tube). Citric acid also can be added to bind calcium. Calcium is an important cofactor for many of the clotting factors. If calcium is then added to a decalcified tube, clotting resumes in 2–3 minutes. If negatively charged phospholipids and a substance such as aluminum silicate (kaolin) is added, the clotting is shorted to less than 1 minute. This is known as the *activated partial thromboplastin time* (aPTT). Another test of coagulation is the *prothrombin time* (PT), which is performed by adding calcium to a decalcified blood sample and then adding thromboplastin (tissue factor and phospholipids). These tests may be performed in the laboratory to detect clotting disorders and are discussed more in internal medicine and laboratory medicine textbooks. For monitoring warfarin treatment the *international normalization ratio* (INR) is recommended. This ratio is derived from a normalization of the PT clotting test. Prothrombin times are reported in seconds and recorded as a ratio of the prothrombin time of the patient to the mean normal prothrombin time of the laboratory and calculated as the international normalized ratio (INR). Because test reagents can differ, the INR is the most reliable way to monitor the prothrombin time (Hirsh, 1991). The PT measurement is converted to the INR using the following formula:

$$\mathrm{INR} = \left[\mathrm{PT}_{\mathrm{PATIENT}}/\mathrm{PT}_{\mathrm{REFERENCE}}\right]^{\mathrm{ISI}}$$

where the PT is the prothrombin time of the patient and reference (from pooled normal blood), and ISI is the international sensitivity index, which is supplied by the manufacturer of the test reagent and indicates the degree of sensitivity of the PT. (In most laboratories the value of ISI is 1.0, simplifying the calculation of this ratio.)

The "gold standard" test for heparin activity is the measure of the plasma factor Xa. This factor is inhibited by heparin and is used for monitoring and adjusting heparin administration to people (Vandiver and Vondracek, 2012). Based on studies in people the therapeutic range for anti-Xa activity is 0.35–0.70 units anti-Xa/ml (Brooks, 2004). Because the aPTT test can produce variable results, the direct factor Xa assay is considered more reliable for monitoring heparin (Brooks, 2004). Despite these advantages, at this time, the direct factor Xa assay is not routinely available in veterinary laboratories and impractical for clinical veterinary medicine (McLaughlin et al., 2017). Moreover, it is a chromogenic assay and can be influenced by other factors that impart color changes in the sample.

More recently, the thromboelastography (TEG) test has been used to diagnose hypo- and hypercoagulable states in animals (Wiinberg et al., 2008). This is a whole-blood assay that tests the viscoelastic properties of clots and provides an assessment of clot forming kinetics and clot strength. The test has become valuable in veterinary medicine to assess hemostasis and is available in many of the large veterinary hospitals.

Other anticoagulant agents used in laboratory examination of blood include sodium oxalate in a concentration of 20% at 0.01 ml/ml (2 mg/ml) blood, and sodium citrate in a concentration of 25% at 0.01 ml/ml (2.5 mg/ml) blood. EDTA (mentioned above in this section) can prevent coagulation when used in a concentration of 1 mg/5 ml blood. Heparin also can be used to prevent coagulation and can be added to a collection syringe (*washing the syringe with heparin)*, added to a collection tube (green tube) or by adding 75 units to each 10 ml whole blood.

Anticoagulants used for blood and blood component transfusions ideally should maintain the function of the individual components and have preservative effects. Such anticoagulant agents include:

1) Acid citrate dextrose (ACD solution), consisting of sodium citrate 25 g, citric acid 8 g, dextrose 24.5 g, and distilled water to make a total volume of 1000 ml, given at the level of 15 ml/100 ml blood. The toxicity of citrated blood injected intravenously varies with rate of injection and total dose. The lethal dose of sodium citrate for the dog is estimated to be about 132 mg/kg after extensive hemorrhage; in the normal intact dog the lethal dose is about 286 mg/kg.
2) Citrate-phosphate-dextrose-adenine (CPDA-1) is one of the most commonly used anticoagulants in human and veterinary transfusion medicine. It can maintain a high level of erythrocyte posttransfusion viability for up to 20 days in dogs (Price et al., 1988).

Heparin

Heparin (heparin calcium and heparin sodium) can be used in vivo and in vitro to inhibit clotting. Heparin has both antithrombotic and anticoagulation effects, which are not necessarily dependent on each other. Heparin is prepared from bovine lung tissue or porcine intestinal mucosa. Both calcium and sodium salts of heparin are available for therapeutic use and occur as a white hygroscopic powder that is easily soluble in water. It is composed of polymers of alternating derivatives of α-ᴅ-glucosamine (*N*-sulfated, *O*-sulfated, or *N*-acetylated) and uronic acid (α-ʟ-iduronic acid or β-ᴅ-glucuronic acid) joined by glycosidic linkages. Heparin used parenterally has a direct and almost instantaneous action on the coagulation process. By contrast, the coumarin derivatives (for oral administration) have an indirect anticoagulant effect by acting as vitamin K antagonists in the hepatic synthesis of select coagulation factors. Subsequently, action by the coumarin derivatives is delayed for several hours.

The medical use of heparin consists of the conventional form of heparin, also called unfractionated heparin (UFH), and the more recent use of low-molecular-weight heparin (LMWH), which is discussed in Section Low-Molecular-Weight Heparins. Unfractionated heparin has a molecular weight of 5,000–30,000 (average 15,000). Heparin sodium is the most common form of UFH. Heparin differs from LMWH by the anti-factor Xa/anti-factor IIa ratio. Heparin has a ratio of 1 : 1, but the LMWHs have ratios of 2 : 1 or higher (ratios are given for each product listed in this chapter).

The action of heparin is to potentiate the action of antithrombin (AT), discussed in Section Natural Anticoagulants. It produces a conformational change in the AT molecule that significantly enhances its inhibitory effect on various activated coagulation factors. The predominant effect of this binding is inhibition of thrombin (factor IIa), as well as factors IXa and Xa, by forming complexes. The action of heparin accelerates the activity of AT by approximately 1,000-fold. This difference in activity between UFH and LMWH is that conventional heparin (UFH) inactivates both factor Xa and thrombin, but LMWHs predominantly inactivate factor Xa because they are not large enough to bind thrombin and AT concurrently. The additional inactivation of thrombin by UFH increases the anticoagulant activity, but also increases the risk of bleeding.

The dose form of heparin is standardized by units rather than mg doses. The standardization is performed by bioassay. In 2009, the standardization underwent changes because of contamination problems in people in 2007–2008 that led to serious adverse events. The contamination problems have been rectified and unitage of heparin is now formulated to an international standard. The United States Pharmacopeia (USP) standard potency is not less than 180 USP heparin units in 1 mg of dried powder.

Indications and Clinical Uses

Heparin is administered to prevent and treat hypercoagulability disorders and prevent coagulation disorders such as thromboembolism, venous thrombosis, disseminated intravascular coagulopathy (DIC), and pulmonary thromboembolism. Use in specific situations in animals is primarily anecdotal or derived from the clinical experience in people. There are few outcome-based studies to evaluate efficacy to support specific guidelines for therapy in veterinary medicine.

Heparin is usually administered subcutaneously (SC) because intramuscular (IM) administration may create a hematoma. After many years of administering heparin to patients with thromboembolic disorders, veterinarians have still not determined the optimal dose or dose frequency. Clinical doses to prevent thrombosis in canine patients with immune-mediated hemolytic anemia (IMHA) has not been effective (50–300 units/kg, SC, q 6 h) but when doses were adjusted based on anti-Xa activity, they were more effective and doses in individual dogs were as high as 560 mg/kg q 6 h. Unfortunately, the anti-Xa assay used in that study is not routinely available in veterinary laboratories. Heparin is also used in horses to prevent thrombosis in patients at risk, but dosage regimens are based on extrapolation from other animals or people, or clinical opinion.

Heparin is definitely *not* a drug for which *one dose fits all.* A fixed dose for every patient will not produce consistent and reliable effects. As the study on treatment of IMHA (Helmond et al., 2010) demonstrated, heparin doses may vary tremendously among patients, depending on the severity of the underlying disease and circulating AT levels (Kidd and Mackman, 2013). A prospective study in dogs with IMHA showed that UFH administered at 300 units/kg SC every 6 hours was generally inadequate to attain the anti-Xa activity in a targeted range (Breuhl et al., 2009). Patients with low AT may not respond as well as those with adequate AT levels. Other variables that may affect the efficacy are variable pharmacokinetics among animals and protein binding. Some clinical syndromes result in low AT levels, which is important to the effectiveness of heparin. Ideally, dose adjustments should be tailored to individual patients by monitoring clotting times. The test most often available to veterinarians is the activated partial thromboplastin time (aPTT). Doses have been adjusted to maintain activated aPTT clotting times at 1.5 to 2.5 times normal. A measurement of anti-factor Xa activity is considered the “gold standard” for determining whether therapeutic UFH doses are attained in people. The target range for anti-Xa activity is 0.35–0.70 units/ml (based on recommendations from human medicine). The problem is that the ideal range for measuring activity in dogs, cats, and horses is not established, and availability of the anti-factor Xa test is not available in most veterinary laboratories. The conclusion in a review paper was that adjusting heparin therapy based on aPTT prolongation does not consistently correlate with anti-Xa activity in dogs (Kidd and Mackman, 2013). In healthy dogs a dose of 500 units/kg SC every 6 hours was not reliable and treatment should be monitored in each patient (Mischke et al., 2001). Because it has been difficult to derive scientifically based dosage regimens, the doses in animals are primarily based on anecdotal uses.

Heparin sodium is available in 1000- and 10,000-units/ml injection vials. For dogs and cats the most common dose used for low-dose prophylaxis is 70 units/kg q 8–12 h SC. For treatment of on-going coagulation problems the dose for dogs is 100–200 units/kg IV loading dose, followed by 100–300 units/kg q 6–8 h SC. The dose is adjusted by monitoring, which may require an increase to 500–600 units/kg if necessary. In more severe cases and high-risk patients, it is recommended to start with 500 units/kg SC as the initial dose, then administer 500 units/kg q 12 h with follow-up monitoring to adjust the dose. To administer a constant rate infusion, use a loading dose of 100 units/kg IV, followed by CRI 18 units/kg/h. The initial dose for cats is 300 units/kg SC, q 8 h. As with dogs, increase to 500 units/kg if necessary.

The typical dose recommended for horses – and used in other large animals – is an initial dose of 150 units/kg SC, followed by 125 units/kg SC q 8–12 h (Moore and Hinchcliff, 1994). These authors discuss the various clinical uses that include jugular vein thrombosis, laminitis, and complications from surgery. The pharmacokinetics in horses are nonlinear and the activity cannot be predicted from plasma heparin pharmacokinetics (McCann et al., 1995). Therefore, monitoring of aPTT is needed to individually adjust the dose. It is important to note that *the doses listed above have not been tested in clinical studies*; they are extrapolated from human medicine or based on recommendations from veterinary specialists.

Adverse Effects

Adverse effects are caused by excessive inhibition of coagulation and produce bleeding problems in patients. Heparin-induced thrombocytopenia, a problem in people, has not been cited as a problem in animals. If excessive anticoagulation and bleeding occur as a result of an overdose, protamine sulfate should be administered to reverse heparin therapy (discussed in Section Reversing Agent for Heparin: Protamine Sulfate). It should not be used in animals unless there is an ability to monitor in order to prevent life-threatening bleeding.

Low-Molecular-Weight Heparins

Low-molecular-weight heparins (LMWH) used in veterinary medicine include tinzaparin (Innohep®), enoxaparin (Lovenox®), and dalteparin (Fragmin®). Most of the veterinary experience has been with dalteparin and enoxaparin. As discussed below, these drugs have several advantages in people over the conventional UFH (Weitz, 1997). These advantages include greater safety, as well as more favorable and predictable pharmacokinetics. However, as described in Section Indications and Clinical Uses, these advantages have not been established for the veterinary uses.

Dalteparin

Dalteparin (Fragmin) is characterized by a molecular weight of approximately 5000, compared to conventional heparin (UFH) with a molecular weight of approximately 15,000. Subsequently, the absorption, clearance, and activity of LMWH differ from UFH. Like the conventional forms of heparin, LMWHs produce their effect by binding to antithrombin (AT) and increasing antithrombin–mediated inhibition of synthesis and activity of coagulation factor Xa. However, LMWH, unlike conventional heparin, produces less inhibition of thrombin (factor IIa). LMWH's activity is described by the anti-factor Xa/anti-factor IIa ratio. For dalteparin, the ratio is 2.7 : 1 (conventional UFH ratio is 1 : 1). In people, LMWHs have several advantages compared to UFH and include greater anti-Xa/IIa activity, more complete and predictable absorption from injection, longer duration, less frequent administration, reduced risk of bleeding, and a more predictable anticoagulant response. However, in dogs and cats, the half-life of LMWH is much shorter than in humans, reducing some of this advantage. In dogs the half-life of dalteparin is approximately 2 hours; in cats it is estimated to be 1.5 hours, which requires much more frequent administration in either species to maintain anti-Xa activity compared to humans. Cats need higher doses and shorter dose intervals than people. Pharmacokinetic properties in horses were similar to humans (Schwarzwald et al., 2002).

Indications and clinical uses Dalteparin, like other LMWHs, is used to treat hypercoagulability disorders and prevent coagulation disorders such as thromboembolism, venous thrombosis, DIC, and pulmonary thromboembolism. Clinical indications are derived from uses of conventional heparin or extrapolated from human medicine. It is not possible to extrapolate doses from a unit-for-unit exchange with other heparins. There have been few clinical studies to examine efficacy of LMWH in animals. Previously published doses extrapolated from humans (100 units/kg q 12 h, SC) have been shown not to produce adequate and consistent anti-Xa activity in dogs and cats (Alwood et al., 2007).

When administering LMWH, aPTT and PT clotting times are not reliable indicators of therapy, although prolonged aPTT is a sign of overdosing. In people, anti-Xa activity is considered the preferred laboratory measure of LMWH activity. Peak anti-Xa activity occurs 2 hours after dosing, and the target range for anti-Xa activity should be 0.5–1.0 U/ml for cats and 0.4–0.8 U/ml for dogs. However, the anti-Xa activity assay is not available in most veterinary hospitals, is impractical, and has produced an inconsistent attainment of the targeted range in dogs (Lynch et al., 2014).

The formulations of dalteparin available are 2500 units anti-factor Xa (16 mg dalteparin sodium) per 0.2 ml in a single-dose syringe; 5000 units anti-factor Xa (32 mg dalteparin sodium) per 0.2 ml in a single-dose syringe; and 10,000 units anti-factor Xa (64 mg dalteparin sodium) per ml in a 9.5 ml multiple-dose vial. The multiple-dose vial should be used within 2 weeks of initial penetration.

Although the doses have not been tested for efficacy, the most commonly recommended dose for dogs is 150–175 U/kg q 8 h SC and, if monitoring is available, doses can be further adjusted. For cats, a dose of 100 units/kg SC every 12 hours failed to produce a sustained anti-factor Xa activity (Alwood et al., 2007) and higher doses of 150 units/kg q 4 h SC, to 180 units/kg q 6 h SC are recommended.

There is even less known for horses, but one dose that has been recommended is 50 units/kg/day SC. The dose may be increased in high-risk patients to 100 units/kg/day. In a study comparing dalteparin in horses to UFH, there were fewer adverse effects with dalteparin, and better efficacy for preventing thrombosis in the dalteparin treatment group (Feige et al., 2003). The dose administered (50 units/kg) produced the desired anti-Xa activity recommended for people (Schwarzwald et al., 2002; Feige et al., 2003).

Adverse reactions and precautions Although better tolerated than conventional heparin, bleeding can be a risk. LMWHs are associated with a lower incidence of heparin-induced thrombocytopenia in people, but heparin-induced thrombocytopenia from any form of heparin has not been a clinical problem in animals. If excessive anticoagulation and bleeding occur as a result of an overdose, protamine sulfate should be administered to reverse heparin therapy (discussed in Section Reversing Agent for Heparin: Protamine Sulfate).

If dalteparin is administered IM, it may produce a hematoma; therefore, SC administration is preferred. Because LMWHs are excreted by renal clearance in animals, if renal disease is present, the elimination will be prolonged. Rebound hypercoagulability may occur after discontinuation of heparin treatment; therefore, it may be advised to taper the dose slowly when discontinuing treatment.

Heparins interact with other drugs and it is not advised to mix these preparations with other injectable drugs. It should be used cautiously in animals that are already receiving other drugs that can interfere with coagulation, such as aspirin, clopidogrel, and warfarin. Although a specific interaction has not been identified, use cautiously in animals that may be receiving certain chondroprotective compounds such as glycosaminoglycans for treatment of arthritis.

Enoxaparin Sodium

In people, enoxaparin has largely replaced dalteparin for routine use. Enoxaparin (Lovenox) is characterized by a molecular weight of approximately 5000, compared to conventional heparin (unfractionated) with a molecular weight of approximately 15,000. Like dalteparin, the absorption, clearance, and activity of LMWH differ from UFH, and like dalteparin the mechanism of action is the same. The anti-factor Xa/anti-factor IIa ratio for enoxaparin is between 3.3 and 5.3 : 1 according to the USP standard, which is higher than dalteparin and higher than conventional UFH that has a ratio of 1 : 1. As with dalteparin, there are several advantages in people for enoxaparin over conventional UFH. But, as found with dalteparin, in dogs and cats the half-life of LMWH is much shorter than in humans, reducing some of this advantage. Similar to studies with dalteparin, cats require higher doses and shorter dose intervals than people (Alwood et al., 2007). In dogs the half-life of enoxaparin is approximately 5 hours (Lunsford et al., 2009); in cats it is estimated to be 1.9 hours, which requires much more frequent administration in either species to maintain anti-Xa activity compared to humans. In horses, the pharmacokinetics are similar to humans (Schwarzwald et al., 2002).

Clinical use Enoxaparin, like other LMWHs, is used for the same indications cited above for dalteparin. As for dalteparin, there have been few studies in animals to examine efficacy of LMWH, and doses extrapolated from humans are not appropriate for animals and are not expected to produce adequate and consistent anti-Xa activity in dogs and cats. As with dalteparin, do not interchange doses on a unit-for-unit basis with heparin or other low-molecular-weight heparins because they differ in manufacturing process, molecular weight distribution, anti-Xa and anti-IIa activities, units, and dosage.

When administering LMWH, aPTT and PT clotting times are not reliable indicators of therapy, although prolonged aPTT is a sign of overdosing. Anti-Xa activity is considered the preferred laboratory measure of LMWH activity in people, but this assay is not widely available for veterinarians, the test is impractical for veterinarians, and the use of this parameter is controversial in animals. Nevertheless, peak anti-Xa activity occurs 3–4 hours after dosing. If the test is available, the target range for anti-Xa activity should be 0.5–1.0 U/ml for cats and 0.5–2.0 U/ml for dogs.

Enoxaparin is available in 30 mg in 0.3 ml, 40 mg in 0.4 ml, 60 mg in 0.6 ml, 80 mg in 0.8 ml, 100 mg in 1 ml injection, 100 mg/ml injection, 120 mg per 0.8 ml, 150 mg/ml injection, and 300 mg per 3 ml. The most common dose for dogs is 0.8 mg/kg SC q 6 h and adjusted with monitoring if possible. At this dose, it consistently maintained target levels of ant-Xa activity (Lunsford et al., 2009). For cats the dose is 1 mg/kg SC q 12 h, up to 1.25 mg/kg SC q 6 h. A dose of 1.5 mg/kg every 6 hours SC was recommended by Alwood et al. (2007) because the lower dose failed to induce sustained anti-factor Xa activity. In horses, the dose used is 0.5 mg/kg q 24 h SC for prophylaxis and 1 mg/kg q 24 h SC for high-risk patients. For horses, 40 units/kg SC once daily has been recommended for prophylactic treatment and increased to 80 units/kg for horses at high risk (Schwarzwald et al., 2002).

Adverse reactions and precautions Although better tolerated than regular heparin, bleeding is a risk as it is with dalteparin. Other precautions and risks are the same as for dalteparin.

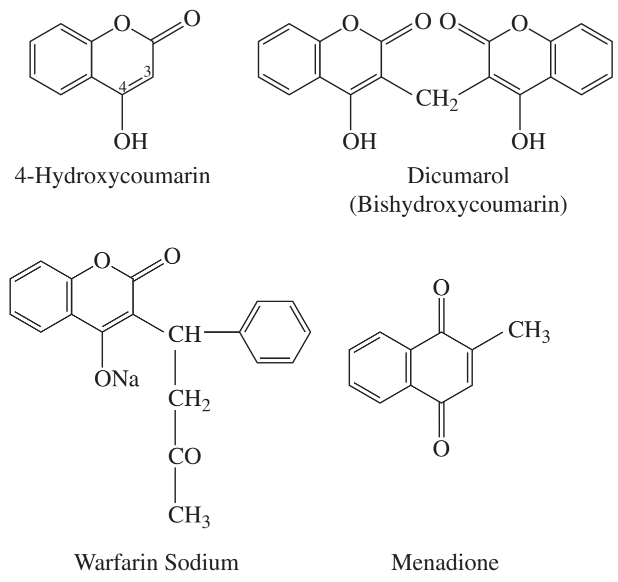
Reversing Agent for Heparin: Protamine Sulfate

Protamine sulfate is a low-molecular-weight protein found in the sperm of certain fish. It is strongly basic and combines with acidic heparin to form a stable inactive salt that prevents further anticoagulant activity of heparin. Protamine is used as an antagonist against heparin-induced hemorrhages. It also arrests action of heparin in vitro. Protamine also has some anticoagulant properties because of interference with the reaction of thrombin and fibrinogen. This would imply that the clinician must take care not to over-neutralize the action of heparin.

Protamine is available as a 1–2% solution. It is administered slowly by the IV route at a rate no greater than 50 mg over a 10-minute period. The dose is 1 mg protamine to neutralize 80–100 units of unfractionated heparin. This is equivalent to approximately 1–1.5 mg to antagonize each 1 mg heparin. The dose to antagonize dalteparin is 1.0 mg protamine for every 100 U dalteparin administered and for enoxaparin the dose is 1 mg protamine for every 1 mg enoxaparin. The dose may need to be adjusted to account for the lapse of time from administration; for example 30 minutes after heparin injection only 0.5 mg protamine may be required to antagonize each 1 mg heparin.

Warfarin and Coumarin Derivatives

Coumarin, normally present in some species of sweet clover, has little anticoagulant action. However, bishydroxycoumarin, a derivative of moldy or spoiled sweet clover, is responsible for hemorrhagic disease in cattle. This compound was synthesized by Link (1943–44). Other drugs have been synthesized with the



4-Hydroxycoumarin

Dicumarol (Bishydroxycoumarin)

Warfarin Sodium

Menadione

4-hydroxycoumarin structure. Of the several coumarin derivatives, bishydroxycoumarin (dicoumarol) was the first oral anticoagulant. In 1948, a much more potent derivative was synthesized as 3-(α-acetonylbenzyl)-4-hydroxycoumarin, but is better known as warfarin. It was FDA approved in 1954 and has been in use ever since then. Warfarin sodium is the most common agent used in this group (marketed as Coumadin®), but all were developed from 4-hydroxycoumarin. The chemical structures of coumarin, dicumarol, warfarin, and menadione are shown in Figure 25.3. Bioavailability of warfarin is much greater than dicumarol because it is approximately 75,000 times more soluble in aqueous media. Warfarin, as well as other vitamin-K antagonists, are still used commonly as rodenticides because they produce fatal internal bleeding. Domestic animals can become inadvertently intoxicated through accidental exposure. Treatment of intoxication is with vitamin K, as discussed in Section Mechanism Of Action.

Mechanism Of Action

Warfarin and the other coumarin derivatives share one major pharmacological action: in vivo inhibition of blood coagulation mechanisms. This activity is achieved by inhibition of hepatic synthesis of vitamin K–dependent clotting factors, that is prothrombin and factors VII, IX, and X (Figure 25.1) (Hirsh, 1991). Therefore, unlike heparin, warfarin is inactive in vitro. The in vivo anticoagulant activity is apparent only after a latent period of at least several hours, which accounts for the time required for natural breakdown of circulating factors already present in the blood (Wajih et al., 2004). After warfarin administration is discontinued, anticoagulant effects can last for several days. This reflects the time necessary for reappearance of newly synthesized clotting factors. The half-life of existing clotting factors varies: factor VII, 6 hours; factor IX, 24 hours; factor X, 36–40 hours; and factor II, 50–60 hours. Because factor VII has the shortest half-life, the test that measures the activity of factor VII will have the greatest ability to detect either subtherapeutic or toxic dosages (PT clotting time and INR, discussed in Section In Vitro Anticoagulants and Clotting Tests). Because factor II has the longest half-life, full antagonist effects of warfarin may not be observed for several days.

The formation of functional clotting factors II, VII, IX, and X is dependent upon the presence of vitamin K. After the precursor proteins of these clotting factors have been synthesized in the liver, they must undergo carboxylation of terminal glutamic acid residues. The carboxylation results in the oxidative inactivation of vitamin K. The resulting vitamin K epoxide is then recycled by epoxide reductase so that it can again participate in the conversion of precursor proteins to functional clotting factors (Figure 25.4). Vitamin K antagonists exert their effect by inhibiting epoxide reductase. This results in a rapid depletion of vitamin K stores. The coagulation factors are still produced but are not functional. Vitamin K and warfarin are mutually antagonistic, and administration of vitamin K can reverse the anticoagulant effects produced by warfarin. The characteristics of warfarin and those of heparin are shown in Table 25.2.

Table 25.2 Pharmacological properties of heparin and warfarin anticoagulants

Characteristic	Heparin	Warfarin
Mechanism of action	Accelerates activity of antithrombin, which inhibits thrombin and activated factors VII, IX, X, XI, and XII	Inhibit hepatic synthesis of vitamin K-dependent clotting factors (II, VII, IX, and X)
Onset of action	Immediate	Delayed 12–24 hours
Duration of action	4 hours	2–5 days
Route of administration	Parenteral	Oral
Laboratory control test	Clotting time, partial thromboplastin time	Prothrombin time
Antidotal therapy	Protamine, fresh blood	Vitamin K, fresh blood or plasma
In vitro activity	Yes	No

Pharmacokinetic Properties

The half-life of warfarin in people is long (36–42 hours), but shorter in animals. In dogs the half-life was 20–24 hours or 14.5 hours (depending on the study) (Neff-Davis et al., 1981). The half-life was 20–30 hours in cats (Smith et al., 2000a). In horses, the half-life was 13.3 hours (Thijssen et al., 1983). In all animals studied (including people) the protein binding is high – greater than 90% (often higher than 95%). Warfarin and other coumarin derivatives are consistently well absorbed orally. Reliable and consistent oral absorption is not associated with predictable activity. Subsequently, there is a large degree in the variability of action and a single fixed dose will not be appropriate for all patients. The variability is caused by differences among animals in metabolism, activity of cytochrome P450 (CYP450) metabolizing enzymes, genetic differences, a possible influence of diet composition (amount of vitamin K), and interaction with other drugs. As summarized in a review by Lesko (2016), in people there is greater than 10-fold intersubject variability in dose requirements. Much of this variability in people can be accounted for by variations in two genes. Genotyping for these genes is now available to test people so that doses of warfarin can be administered to people with greater precision. However, these tests are not available for animals.

Clinical Use, Administration, and Monitoring

Because of the variable action among animals, requirement for monitoring, and availability of other drugs, these agents are not used commonly in veterinary medicine today. There are there are no clinical trials that have shown efficacy for hypercoagulation states in animals. In older guidelines, warfarin was recommended for small animals to prevent thromboembolism from a variety of diseases, especially heart disease. In horses, warfarin was once recommended to treat navicular disease, although it is no longer popular for this use.

The high variability in individual and species response to warfarin necessitates laboratory monitoring of prothrombin activity for safe and effective clinical use. Contraindications include bleeding from any cause, purpura of any type, or a severe state of malnutrition.

Warfarin response can be highly variable among animals. Pharmacokinetic studies have attempted to correlate plasma pharmacokinetics with clinical response (prothrombin time [PT]) (Neff-Davis et al., 1981). However, such a correlation has been difficult to demonstrate. A specific dose and plasma concentration that produces an effective prolongation of prothrombin time in one patient may not be effective in another individual. Because of the variation in response, adjustment of doses by monitoring bleeding times in treated animals is needed, but rarely performed clinically.

Because the optimum dose should be identified for each patient, the best method to monitor warfarin therapy is with the one-stage PT and INR (discussed in Section In Vitro Anticoagulants and Clotting Tests). In animals, the dose is adjusted to maintain PT at 1.5 to 2 times normal (or INR of 2–3). Warfarin sodium is available in 1, 2, 2.5, 4, 5, 7.5, and 10-mg tablets. Warfarin sodium is soluble in water. It is light sensitive and should be packaged in containers that protect the medication from light and moisture. Solutions should have a pH greater than 8 to maintain solubility. Some tablets do not have the drug distributed evenly; therefore, uneven doses can result from splitting tablets. When dividing tablets for treatment, it is best to crush up a whole tablet into a powder and divide the doses equally from the powder.

For a rapid effect in dogs consider a loading dose of 6 mg per dog, once daily, for two treatments in order to achieve the targeted INR (Monnet and Morgan, 2000). A typical dose for dogs is 0.1–0.2 mg/kg q 24 h PO. Start with this dose q 12 h for the first 2–4 days because of a lag time before maximum effect is observed. For cats, start with 0.25 to 0.5 mg/cat/day and adjust dose based on bleeding time assessment (equivalent to 0.06 to 0.09 mg/kg). Adjust dose by monitoring clotting time. When cats were administered 0.5 mg/kg the maximum response occurred in 24–48 hours (Smith et al., 2000b). The median dose to produce therapeutic concentrations was 0.06–0.09 mg/kg/day. However, the concentration needed to produce the targeted INR value of 2–3 was highly variable among cats. There was wide variation in pharmacokinetics and response.

For horses, administer 0.02 mg/kg q 24 h PO (9 mg per 450 kg of body weight [1000 pounds]). Increase this dose gradually (by increments of 20%) until a 2 to 4-second increase in PT bleeding time is achieved. Allow 7 days between changes in dose. After a dose of 0.75 mg/kg the effect of warfarin in horses was noticed only after 60 hours and lasted for approximately 30 hours (Thijssen et al., 1983).

Adverse Effects and Precautions

Adverse effects are attributable to decreased blood clotting. In people, it is among the top 10 drugs causing serious or fatal adverse drug reactions. (Dabigatran, discussed in Section Thrombin Inhibitors**,** is also in the top 10.) Spontaneous bleeding can result in blood loss, hemoperitoneum, hemarthrosis, gastrointestinal bleeding, epistaxis, and excessive bleeding from trauma or surgery.

Multiple drugs and some foods may affect warfarin's action (Daly and King, 2003). Some of these that may potentiate warfarin's action include aspirin, clopidogrel, chloramphenicol, phenylbutazone, ketoconazole, and cimetidine. Drugs that induce liver enzymes may accelerate metabolism (e.g., phenobarbital, griseofulvin, rifampin). Drug interactions are possible if administered with other highly protein-bound drugs, but such reactions are poorly documented in animals. Drug interactions are also possible with trimethoprim, sulfonamides, and metronidazole. Do not administer with some cephalosporin drugs (particularly those with *N*-methylthiotetrazole, NMTT) because cephalosporins may induce bleeding through antivitamin K–dependent mechanisms.

Long-acting Rodenticides

In addition to warfarin, there are other rodenticide derivatives, sometimes called second-generation rodenticides. These include *bromadiolone, brodifacoum, diphenadione, chlorophacinone*, and *pindone*. These are not used therapeutically but are found in the long-acting rodenticides. Animals may become inadvertently exposed through poisoning. Because their effects can persist for many days, and even weeks, treatment with warfarin antagonists (vitamin K) must continue for as long as 6 weeks until clotting times return to normal ranges. Specific instruction on treatment of poisoning from these rodenticides is found in internal medicine and toxicology textbooks, or by contacting an animal poison control center.

Thrombin Inhibitors

The inhibition of thrombin (Figure 25.1) is a key role in producing anticoagulant effects Thrombin is a logical target because it is involved in the final step in coagulation and thrombin is also an activator of platelets. Thrombin also stimulates further coagulation by activating cofactors V and VIII (Table 25.1). One of the first direct thrombin inhibitors was ximelagatran. It was briefly on the market until the hepatic toxicity associated with its use required withdrawal.

Dabigatran etexilate (Pradaxa®) is the most promising of the thrombin inhibitors at this time (Table 25.3). There is little information on its use in animals. In people it has oral bioavailability of only 6%. The ester dabigatran etexilate is converted to dabigatran quickly by esterases. More detailed pharmacokinetic features are listed in the paper by Gong and Kim (2013). Most of dabigatran is eliminated unchanged in the urine; therefore, it is less subject to drug metabolizing interactions.

There has not been published reports of clinical use of dabigatran in veterinary medicine. Some use, and doses, have been extrapolated from the experience in human medicine (see Table 25.3 for dosages.)

Table 25.3 New anticoagulant drugs

	Drug		
	Dabigatran etexilate	**Rivaroxaban**	**Apixaban**
Brand name	Pradaxa	Xarelto	Eliquis
Target	Thrombin	Factor Xa	Factor Xa
Prodrug	Yes	No	No
Monitoring required	No	No	No
Half-life (people)[a]	12–17 hours	5–9 hours	8–15 hours
Human dose	150 mg twice daily	20 mg once daily	5 mg twice daily
Interactions possible?[a,b]	p-glycoprotein inhibitors and inducers[c] may affect oral absorption	CYP 450 inhibitors, and p-glycoprotein inhibitors[c]	Potent CYP 450 inhibitors[c]

[*] Other pharmacokinetic features and drug interactions in people can be found in the review by Gong and Kim (2013).

[†] Interactions possible are listed for people. These are possible in animals but specific studies have not been performed.

[‡] Examples of inhibitors may include ketoconazole, diltiazem, and macrolide antibiotics.

Examples of inducers include rifampin and phenobarbital.

One of the disadvantages of new anticoagulant drugs has been bleeding problems and the inability to reverse these effects. On the other hand, warfarin is effectively reversed with vitamin K administration. However, recently a new reversal agent became available for dabigatran, idarucizumab (Praxbind®). This agent is approved for urgent reversal of the anticoagulant effect of dabigatran etexilate. Idarucizumab is the first such specific reversal agent to become available for one of the new oral anticoagulants.

In people, more adverse reaction reports were generated with the use of dabigatran than the other new agents (listed in Section Factor Xa Inhibitors). There is a relatively high rate of gastrointestinal problems from oral dabigatran. It requires an acid environment for oral absorption and an acidifier is included in the formulation. This has caused dyspepsia in some people and the need to switch to another medication.

Factor Xa Inhibitors

Rivaroxaban and Apixaban

The inhibition of the active form of factor X (Xa) is also an attractive target for treating clotting disorders. Factor Xa plays a key role in the activation of the clotting cascade (Figure 25.1). The structure of Factor Xa is similar, but not identical, in dogs and humans, indicating that Factor Xa inhibitors used in people might be effective in dogs. Direct factor Xa inhibitors include rivaroxaban (Xarelto®) and apixaban (Eliquis®), both of which have become popular in human medicine (Table 25.3). The newest agent in this group is edoxaban (Savaysa®). In theory, the inhibition of Xa produces less bleeding adverse events than inhibition of thrombin, but this has not been shown in human trials.

These new agents have several advantages over warfarin. The pharmacokinetics are predictable and a fixed dose may be administered to produce results without routine monitoring as required for warfarin. They are not affected by dietary changes, and are less subject to drug interactions, although some are possible. More detailed pharmacokinetic features are listed in the paper by Gong and Kim (2013).

Dabigatran (discussed in Section Thrombin Inhibitors) and the factor Xa inhibitors are primarily for oral use to prevent thromboembolism associated with atrial fibrillation in people. The clinical effectiveness of these three new agents appears similar (Potpara and Lip, 2011; Mantha et al., 2013). These agents are also used for venous thrombosis, such as deep vein thrombosis, but only rivaroxaban is approved for this indication.

There have been some limited reports of the use of rivaroxaban and apixaban in dogs and cats. Dogs with immune-mediated hemolytic anemia (IMHA) are prone to thromboembolism and they typically have poor response to antiplatelet therapy, heparin, and LMWH (Kidd and Mackman, 2012). Because of lack of other alternatives for treating IMHA-associated thromboembolism, new agents such as rivaroxaban have been examined. Rivaroxaban was administered to dogs at an average dose of 0.89 mg/kg once daily (Morassi et al., 2016). It was well tolerated in this small group of dogs. There were no significant differences among treatment groups; therefore, it was not possible to determine if rivaroxaban was more beneficial than standard antiplatelet therapy. In limited case reports (Yang et al., 2016) rivaroxaban was administered to dogs for treatment of thrombotic complications at oral doses of 0.5–1 mg/kg once daily, with mixed results.

The pharmacokinetics and pharmacodynamics of oral apixaban have been studied in healthy cats (Myers et al., 2015). The half-life after oral administration of 0.2 mg/kg was approximately 3 hours and bioavailability was 86%. The half-life in other species is similar, but was longer in people (Table 25.3). It was an effective inhibitor of factor Xa in the cats and activity was correlated with plasma drug concentrations. However, because of the short half-life, it would be difficult to maintain anticoagulant activity with twice-daily administration. Oral absorption is at least 50% in dogs (He et al., 2011).

The most detailed study with rivaroxaban has been in cats (Dixon-Jimenez et al., 2016). Cats were treated at three doses (1.25, 2.5, and 5 mg/kg) for pharmacokinetic studies. Oral doses were also administered every 12 or 24 hours for 3, 7, or 28 days for coagulation analysis. The doses were well tolerated and there were dose-related changes in clotting times and factor Xa inhibition. The half-life of rivaroxaban in cats was 7.55 hours (± 3.1 hours). At the doses studied in cats, the anti-Xa activity was not maintained in the human therapeutic range throughout the duration of a 12- or 24-hour interval. Until other studies are available, doses higher than 2.5 mg/kg twice daily are recommended for testing.

Rivaroxaban also has pharmacokinetics that were unfavorable in dogs (Weinz et al., 2005). Although oral absorption is good, the half-life is short (1 hour). Despite the short plasma half-life, a study in healthy Beagle dogs that measured anticoagulant activity concluded that a dose of 2 mg/kg twice, at 8 hour intervals maintained anticoagulant activity for a 24 hour interval (Conversy et al., 2017).

Adverse Effects and Precautions

One of the disadvantages of new anticoagulant drugs has been bleeding problems and the inability to reverse the effects. Warfarin can be reversed with vitamin K. A new reversal agent for dabigatran (idarucizumab) has only recently become available, but has not been used in animals. A new agent, andexanet, is being developed for antagonizing effects of Factor Xa inhibitors. Other adverse effects are derived from the human use, because there has not been enough experience with these drugs to know the adverse effects in animals. In short-term studies they have been well tolerated. Because of the short half-life of these drugs compared to warfarin, there is a concern that missed doses could lead to thromboembolic risks.

Agents to Reverse Warfarin/ Coumarin

Vitamin K

Vitamin K is a fat-soluble vitamin that is found in a variety of plants and is also produced by microorganisms. Its main therapeutic usage is in the treatment of vitamin K antagonist rodenticide intoxication. Vitamin K is a cofactor used to synthesize coagulation factors in the liver (factors II, VII, IX, and X) (Figure 25.4). It also is vital for the production of active protein C and protein S, both of which have anticoagulant effects.

Vitamin K_1 (phytonadione) is present in plants, vitamin K_2 (menaquinone) is produced by microorganisms, and vitamin K_3 (menadione) is a synthetic derivative (Figure 25.3). Vitamin K_1 is the most immediately available fat-soluble vitamin used to treat coagulopathies caused by anticoagulant toxicosis (warfarin or other rodenticides). These anticoagulants deplete vitamin K in the body, which is essential for synthesis of clotting factors.

Vitamin K_1 is also known as phytonadione and phylloquinone (phytomenadione is the British spelling of phytonadione). Vitamin K_2 is also known as menaquinone. Vitamin K_3 is known as menadione. Vitamin K_3 is a synthetic analogue and is not equivalent to Vitamin K_1, and is not recommended for clinical use. Vitamin K_3 has demonstrated poor efficacy in veterinary patients as well as demonstrating toxic side effects (Alstad et al., 1985; Fernandez et al., 1984).

Phytonadione and phytomenadione are synthetic lipid-soluble forms of vitamin K_1. Menadiol is vitamin K_4, which is a water-soluble derivative converted in the body to vitamin K_3 (menadione). Other forms of vitamin K may not be as rapidly acting as vitamin K_1; therefore consider using a specific preparation.

Vitamin K_1 is actively absorbed in the small intestine. Vitamins K_2 and K_3 are passively absorbed in the ileum and colon. Solubilization by bile acids is required for absorption of vitamins K_1 and K_2. Biotransformation in the organism is required for vitamin K_3 to become active (Mount, 1982).

Indications and clinical uses The phytonadione form of vitamin K_1 is used to treat coagulopathies caused by anticoagulant toxicosis (warfarin or other rodenticides). In large animals, it is used to treat sweet clover poisoning. Vitamin K_1 is preferred for acute therapy because it is more highly bioavailable. When treating poisoning caused by rodenticides, consult a poison control center for the protocol if the specific rodenticide is identified. Some long-acting rodenticides require prolonged treatment (6 weeks) and identification of the specific agent is important. Because this is a fat-soluble vitamin, the oral forms of vitamin K_1 should be administered with food to enhance absorption. The preferred route for initial treatment is SC, but IM also can be used. When treating for poisoning by second-generation rodenticides, which have long half-lives, 6 weeks of therapy may be necessary. If an injection is used, it can be diluted in 5% dextrose or 0.9% saline but not other solutions. Although vitamin K_1 veterinary labels have listed the intravenous route for administration, these labels have not been approved by the FDA. Therefore, avoid intravenous administration of vitamin K_1.

Monitoring treatment of poisoning is important to ensure proper duration. Monitoring the clotting times (as discussed in Section Clinical Use, Administration, and Monitoring) can be used as a guide. Factor VII is the vitamin K-dependent clotting factor with the shortest half-life and is also the factor predominantly measured by PT. As a result, PT values will change before other clotting time tests.

The typical dose of Vitamin K_1 for dogs and cats for treatment of short-acting rodenticides is 1 mg/kg/day for 10–14 days IV, SC, or oral. For treatment of long-acting rodenticides administer 2.5–5 mg/kg/day for 3–4 weeks IM, SC, or PO. For cattle, calves, horses, sheep, and goats, the dose is 0.5–2.5 mg/kg SC or IM.

Adverse reactions and precautionary information In people, a rare hypersensitivity-like reaction has been observed after rapid intravenous injection. This reaction may be caused by histamine release from a reaction to the drug vehicle, Polysorbate 80. Signs resemble anaphylactic shock. These signs also have been observed in animals. To avoid anaphylactic reactions, do not administer IV. Reactions from intramuscular injection, such as hematoma, may occur in animals with coagulopathies.

Agents for Treating Coagulopathies

Desmopressin Acetate

Desmopressin acetate (DDAVP) is a synthetic analog of vasopressin, and is used in the treatment of central diabetes insipidus and to transiently elevate levels of vWF. (See Chapter 26 for endocrine uses.) Its actions to increase vWF are via the V_2 receptor rather than the V_1 receptor. The V_1 receptor is the vascular receptor that is responsible for vasoconstriction. The elevation in vWF allows surgical procedures to be performed and aids in the control of capillary bleeding from wounds in humans and animals with certain forms of von Willebrand disease. In comparison to vasopressin, DDAVP has minimal pressor effects. When DDAVP is administered, it releases stored vWF from endothelial cells and macrophages and produces a rapid rise in vWF levels, with larger, more-active multimers predominating (Kraus et al., 1989; Johnstone and Crane, 1986). This effect is reduced if the drug is given repeatedly, because the storage pools will be depleted. The duration of elevation is approximately 2 hours (Mansell and Parry, 1991). Though the elevation in vWF levels found in dogs is considerably lower than in humans, clinically a decrease in buccal mucosal bleeding time was seen (Kraus et al., 1989), but in some dogs only a minimal response was noted. The recommended dosages for dogs for von Willebrand's disease treatment is 1 μg/kg (0.01 ml/kg), administered SC, or diluted in 20 ml of saline and administered over 10 minutes IV.

Antiplatelet Drugs

Platelets have a central role in the initiation and propagation of thrombus formation (Figure 25.2). They release a variety of substances that promote coagulation, and they also form the initial platelet plug. Platelets adhere and aggregate in response to a myriad of stimuli. A central mechanism in aggregation is alteration of cAMP concentrations in the platelet itself. Increased cAMP is inhibitory to aggregation, while decreased cAMP is proaggregatory. Our ability to study antiplatelet drugs is enhanced by the improved availability of platelet activity tests such as thromboelastography (TEG), platelet aggregometry, and the Platelet Function Analyzer 100. These test systems are available in research laboratories of veterinary scientists who study these drugs and in many veterinary hospitals that treat critically ill patients with clotting disorders. The specific tests and their interpretation will not be discussed here but are available in various internal medicine and critical care books.

A variety of drugs can be used to reduce platelet function. Clinically this should be beneficial in the prevention of thrombotic disease, especially if the clot forms on the arterial side of the vascular system. The efficacy of these drugs in the prevention of myocardial infarction and stroke in humans has been well established and some of the drugs and strategies have been adapted from human medicine. The most common indications in veterinary medicine are to prevent thrombi associated with feline cardiomyopathy and to reduce the severity of pulmonary endarteritis associated with heartworm disease. Although work in the 1980s promoted the use of aspirin as an antiplatelet drug for alleviating the proliferative changes in arteries associated with heartworm infestation (Boudreaux et al., 1991; Keith et al., 1983; Schaub et al., 1983), this indication no longer has support. The American Heartworm Society no longer recommends aspirin treatment for canine heartworm disease patients because convincing evidence of clinical benefit is lacking and some research indicating that aspirin treatment may produce harm (https://www.heartwormsociety.org/). Platelet inhibition is potentially beneficial for other diseases such as membranous glomerulonephritis, mild DIC, pulmonary thromboembolism, and vasculitis, but protocols are not fully developed for all these indications. In horses, platelet inhibition may be of benefit in the treatment of thrombotic disorders such as laminitis and navicular disease.

Aspirin

A commonly used antiplatelet drug is aspirin (acetylsalicylic acid, ASA). Aspirin is a nonsteroidal antiinflammatory drug (NSAID) that inhibits the activity of cyclooxygenase (discussed in detail in Chapter 20.). Other NSAIDs, discussed in Chapter 20, inhibit the enzyme cyclooxygenase, but are not as specific as aspirin for COX-1, the predominant enzyme found in platelets. Aspirin is unique in that even at low doses it causes irreversible inhibition of platelet cyclooxygenase. The acetyl-group on aspirin acetylates cyclooxygenase in platelets and blocks the synthesis of thromboxane A_2 (TXA_2). By contrast, prostacyclin (PGI_2) synthesis by the vascular endothelium is mediated by COX-2 and is not affected by low doses of aspirin. Thromboxane A_2 and PGI_2 have opposing actions on platelet function and vascular smooth muscle tone. Prostacyclin is a potent vasodilator and inhibitor of aggregation, while TXA_2 is a vasoconstrictor and stimulates platelet aggregation.

After oral administration, aspirin is absorbed into the portal vein where most of the platelet acetylation of COX-1 in platelets takes place. Subsequently, aspirin enters the liver where it is rapidly converted to salicylic acid. Therefore, most acetylation in platelets occurs in the portal circulation where aspirin levels are the highest and acetylation of COX-1 can occur. The COX-2 enzyme in the vascular endothelium that synthesizes PGI_2 is exposed to primarily salicylic acid, not aspirin. Because platelets do not synthesize new enzymes (platelets have no nucleus), this results in decreased platelet aggregation throughout the lifespan of the platelet. Aggregation response will return to normal as new platelets enter the bloodstream from the bone marrow. If endothelial cell cyclooxygenase activity (PGI_2) is inhibited, it recovers more rapidly because new enzyme can be synthesized. Theoretically, at low aspirin doses this selective inhibition of COX-1 over COX-2 is maintained, producing a specific antiplatelet effect, but at high doses the selectivity is diminished. In addition, low dosages should minimize the gastrointestinal side effects that can occur following aspirin administration. This theoretical basis for antiplatelet aspirin dosages notwithstanding, the goal of finding an optimum low aspirin dose has proven elusive. Studies of the effect of aspirin on ADP or collagen-induced canine platelet aggregation do not reliably show a decrease in aggregation and, consequently, use of aspirin alone may be suboptimal for thromboprophylaxis in some dogs (Brainard et al., 2007). Experimental infestation and embolization with heartworms lead to a pronounced increase in the amount of aspirin needed to maintain this level of inhibition (Boudreaux et al., 1991).

Dosage recommendations for platelet inhibition vary widely. In healthy dogs a dose of 0.5 mg/kg twice daily aspirin was found to be more effective than higher doses (Rackear et al., 1988). But many dogs do not respond to low-dose aspirin and as many as 30% are not responsive. More frequent dosing was needed to produce a consistent response (Rackear et al., 1988).

In cats 25 mg/kg twice weekly has been found to inhibit platelet aggregation without evidence of toxicity (Greene, 1985). However, aspirin produces inconsistent antiplatelet effects in cats. Platelets collected from cats ex vivo after treatment with aspirin (5 mg/kg) had decreased thromboxane production (TXA_2) but platelet aggregation was not affected. Doses of 5 mg or 20.25 mg to cats every 72 hours produced inconsistent response and was not as effective as clopidogrel (Ho et al., 2016). Treatment with 81 mg per cat every 3 days has not been as effective for preventing arterial thromboembolism compared to clopidogrel (Hogan et al., 2015).

Experimental studies in horses showed that oral aspirin (12 mg/kg) significantly increased bleeding times for 48 hours posttreatment (Trujillo et al., 1981). A lower dose (4 mg/kg) prolonged bleeding times for 4 hours posttreatment (Cambridge et al., 1991).

Clinical use and dosages Despite the inconsistent results and variable activity, aspirin continues to be used by veterinarians as an antiplatelet agent. Although the optimum dose is not determined, low doses of aspirin are routinely used for antiplatelet therapy. Addition of other antiplatelet drugs such as clopidogrel (Plavix®, discussed in Section Clopidogrel) provides more effective inhibition and sometimes aspirin and clopidogrel are used together. Clinical doses are varied because of inconsistency of experimental results. Doses have ranged from 0.5 mg/kg every 12 hours, up to 5–10 mg/kg. Doses for cats have ranged from 5 mg per cat q 72 h, to 81 mg per cat q 72 h. In cats, a dose of 81 mg per cat is common (size of a typical children's aspirin tablet) every other day for convenience. A study to monitor long-term management of cats at risk for arterial thromboembolism did not identify a difference between a high dose (81 mg per cat) and a low dose (5 mg per cat) every 72 hours (Smith et al., 2003).

Clopidogrel

Clopidogrel is structurally related to ticlopidine, which exerts similar antiaggregation mechanisms. Clopidogrel (Plavix) is a prodrug that undergoes biotransformation into its active metabolite (Brainard et al., 2010). The active metabolite is a P2Y12 receptor inhibitor, thereby preventing ADP from exerting its strong cyclic AMP-dependent aggregating action (Figure 25.2). Its onset of action is therefore slow, but it seems to have fewer objectionable side effects than does ticlopidine. Clopidogrel is commonly used in conjunction with aspirin, and it has been approved for use in humans to prevent recurrence of stroke and myocardial infarction secondary to thrombus formation.

Clopidogrel is primarily metabolized by two main pathways, one leading to the formation of the inactive carboxylic acid metabolite (SR26334), and one leading to the active metabolite, a thiol derivate, through formation of 2-oxo-clopidogrel (Pereillo et al., 2002). This active metabolite is responsible for the antiplatelet effects (Savi et al., 2000). In humans, conversion to the active metabolite occurs via cytochrome P450 enzymes, including CYP2C19, CYP3A4, CYP1A2, and CYP2B6 (Mega et al., 2009). CYP2C19, considered the main enzyme in people, can be inhibited by some drug therapies, such as proton pump inhibitors (omeprazole) (Mega et al., 2009; Simon et al., 2009). Variable results for clopidogrel efficacy in people have been attributed to CYP2C19 polymorphisms (Samant et al., 2017). Although dogs are known to have CYP2C19, CYP3A4, CYP1A2, and CYP2B6 activity (Chauret et al., 1997), it is not known if dogs share the same metabolic pathway for clopidogrel as humans. Administration of omeprazole to dogs did not affect clopidogrel antiplatelet activity (discussed in Chapter 46). In humans, the active metabolite is subsequently converted to an inactive metabolite. Concentrations of the parent drug and active metabolite are usually undetectable in plasma (Brainard et al., 2010). Therefore, measurement of the inactive, carboxylic acid metabolite has been used as a surrogate marker to assess clopidogrel pharmacokinetics (Bahrami et al., 2008). In people, the inactive carboxylic acid metabolite represents 85% of the circulating metabolite.

Clinical use Because of the inconsistency of aspirin as an antiplatelet drug in animals, and the lower cost of the human form of clopidogrel after it became available as a generic tablet, interest in veterinary use has increased. It is used as an antiplatelet drug for patients with heart disease, thromboembolic disorders, heartworm disease, immune-mediated hemolytic anemia, and cats at risk of cardiogenic arterial thromboembolism. This drug has been safely administered to cats, rabbits, dogs, and calves (Brainard et al., 2007, 2010; Hogan et al., 2004; Wong et al., 2009; Coomber et al., 2006; Hong et al., 2005).

The use of clopidogrel is now common in dogs and cats. In dog, cats, and horses, oral administration has produced significant inhibitory effects on platelets that are superior to aspirin. A dose of either 0.5 or 1 mg/kg oral per day in dogs consistently produced a rapid and effective inhibition of canine platelet aggregation responses to both ADP and collagen. The effect of clopidogrel on the platelets of dogs appears to be irreversible (Brainard et al., 2010). In dogs, a dose of either 0.5 or 1.0 mg/kg, decreased ADP-induced platelet aggregation occurs for 3 days after discontinuation of drug administration in some dogs and longer than 7 days in others. Effects also persisted in cats for 3 days after administration. At 2 mg/kg orally, q 24 h, clopidogrel significantly suppressed platelet activity in horses, which persisted for 6 days after the last dose.

The sustained activity of clopidogrel may allow intermittent dosing (for example every other day) in clinical patients. The effect on ADP-induced aggregation was most profound, indicating that the drug is able to exert an effect at the canine $P2Y_{12}$ ADP receptor. In some dogs (which may have variants of the $P2Y_{12}$ receptor), clopidogrel activity may be absent or diminished, similar to responses reported in humans with polymorphisms in this receptor (Feher et al., 2010).

The tablet is a fixed dose of 75 mg. Therefore, either a whole tablet, or fraction of a tablet is used for treatment to simplify dosing. For example, the dose in cats is 18.75 mg per cat (1/4 tablet) q 24 h PO. Smaller doses may be effective but have not been evaluated in cats. For dogs a dose of 1–2 mg/kg q 24 h PO is used. An oral loading dose may be given at 2–4 mg/kg followed by 1–2 mg/kg q 24 h PO. (In some cases, a higher oral loading dose of 10 mg/kg has been used.) For horses, the loading dose is 4 mg/kg, followed by 2 mg/kg PO q 24 h.

Ticlopidine

Ticlopidine (Ticlid®) is also a $P2Y_{12}$ receptor inhibitor. Because of the availability of clopidogrel and more extensive information regarding the effects and dosage regimens in animals, ticlopidine is rarely used in veterinary medicine. Ticlopidine should not be used in cats because it produces adverse reactions.

Fibrinolytic Agents

Thrombolytic therapy is not preformed commonly in veterinary medicine. Use of these agents is expensive, and there is little evidence available to show that the benefits outweigh the risks and expense. Although it is an important component of the emergency treatment in people for acute ischemic strokes, myocardial infarction, deep vein thrombosis, and pulmonary thromboembolism, it has not been very successful in animals. The most common clinical presentations where this treatment is considered is feline arterial thromboembolism (Fuentes, 2012; Lunsford and Mackin, 2007) and canine pulmonary thromboembolism. These conditions are typically secondary to other problems (heart disease, heartworm disease, autoimmune disease) (Thompson et al., 2001). Pharmacological acceleration of fibrinolysis involves drugs that enhance the conversion of the inactive precursor plasminogen to the active fibrinolytic enzyme plasmin (Armstrong et al., 2003). Plasminogen exists in two phases, the plasma or soluble phase found in the circulating blood and the gel phase bound to fibrin in the formed clot. Thus when a plasminogen-activating agent comes in contact with the clot, fibrin-bound gel-phase plasminogen is activated to plasmin locally with selective fibrinolysis. There is increased tendency for systemic bleeding if, instead, soluble-phase plasminogen circulating in systemic blood is also activated. Plasmin formation would then occur throughout the circulation rather than being localized to the formed clot. Indeed, the presence of plasmin in peripheral blood indicates a pathological fibrinolytic state. Such a condition reflects over-activation of plasminogen, which overcomes the neutralizing capacity of an endogenous antagonist to plasmin called α_2-antiplasmin.

Streptokinase

Streptokinase is a stable, vacuum-dried powder containing enzymes produced by β-hemolytic *Streptococcus*. Streptokinase complexes with plasminogen, yielding plasmin. Streptokinase converts both circulating plasminogen as well as plasminogen associated with a thrombus. Therefore, systemic administration can produce wide-spread inhibition of clotting.

The most common use recorded in veterinary medicine is treatment of arterial thromboemboli in cats and pulmonary thromboembolism in dogs (Moore et al., 2000; Fuentes, 2012; Killingsworth et al., 1986; Thompson et al., 2001). A dose of 90,000 units administered IV to cats, followed by 45,000 units per hour, produced a systemic fibrinolytic state but did not reduce size of clots (Killingsworth et al., 1986). An average dose of 18,857 units/kg administered to cats with arterial thromboembolism may have provided a benefit in some cats but there was not a comparison group to compare effects of nonstreptokinase treatment (Moore et al., 2000). Some cats developed life-threatening hyperkalemia after treatment. There was no relationship between survival and dose administered. In other case reports reviewed by Lunsford and Mackin (2007), describing the use of streptokinase in cats, there were serious complications associated with the use, including death. The explanation for treatment failure is that cats with arterial thromboembolism have clinical signs caused by vasoactive substances (e.g., thromboxane and serotonin), and not directly attributed to the clot. Dissolving the clot does not mitigate the effects of the vasoactive substances, and can lead to reperfusion injury.

Streptokinase has had limited use in dogs, primarily for pulmonary thromboembolism. Published studies have been based on small numbers and not enough to determine if it is successful (Thompson et al., 2001). Doses administered have been 90,000 units per dog, followed by 45,000 units per dog, IV. Based on these experiences, until more information becomes available streptokinase treatment cannot be recommended as a routine treatment. It has also been used in large animals, but clinical study results are lacking. The daily dose for large animals is 5,000–10,000 units/45 kg.

Urokinase is isolated from fetal kidney cells in tissue culture. It has a similar effect as streptokinase, but there has been no recorded successful use in veterinary medicine.

Tissue Plasminogen Activator

Tissue-type plasminogen activator (t-PA) predominantly exerts its effect in association with fibrin clots. It binds to fibrin in a thrombus and converts the entrapped plasminogen to plasmin, thereby initiating local fibrinolysis. Unlike other plasminogen activators, t-PA does not readily induce a systemic fibrinolytic state and has less systemic bleeding problems than streptokinase. Therefore, the safety advantage of t-PA over streptokinase makes this a more attractive treatment. The currently available commercial product is recombinant DNA produced human-type tissue plasminogen activator (often referred to as rt-PA). This product, called Aletplase®, is produced by recombinant DNA technology synthesized using the complementary DNA (cDNA) for natural human tissue-type plasminogen activator (t-PA) obtained from an established human cell line.

There are only a few papers that have reported on the experience of administering t-PA to animals, mostly in cats with arterial thromboembolism (Thompson et al., 2001; Lunsford and Mackin, 2007). In cats with thromboembolism, a dose of 0.25–1 mg/kg per hour for a total dose of 1–10 mg/kg was associated with resolution of clots in some cats. Although intravenous administration of t-PA resulted in a rapid return of function in some cats, 50% of the animals treated died acutely after treatment (Pion, 1988). This was attributed to the rapid reperfusion of the rear extremities, which resulted in reperfusion-induced hyperkalemia and heart failure. There is no other clear evidence that supports the use of t-PA for treatment in cats (Lunsford and Mackin, 2007). The use in dogs has been reported only in isolated cases (1 mg/kg IV) and produced clinical benefits in these instances (Thompson et al., 2001).

Antifibrinolytic Drugs

Fibrinolysis produces breakdown of fibrin clots through conversion of plasminogen to plasmin. Ordinarily, in normal conditions there is a balance between clot-forming processes and fibrinolysis. Excessive fibrinolysis can lead to excessive bleeding disorders.

Drugs available for treatment of hyperfibrinolytic conditions are aminocaproic acid and tranexamic acid. These are synthetic lysine compounds that decrease fibrinolysis by binding to fibrin and competing for lysine-binding sites to inhibit plasminogen and plasmin. Aminocaproic acid prevents the association of fibrin with plasminogen. Concentrations needed to completely inhibit fibrinolysis in canine plasma after induction of hyperfibrinolysis were determined by Fletcher et al., (2014). Aminocaproic Acid (Amicar®), is available as 100- and 500- mg tablets, 250 mg/ml syrup, and 250 mg/ml for IV injection. There is limited information on the use of these products in animals. They are used anecdotally, but uses and doses are extrapolated from human medicine. In research animals, 100 mg/kg or 20 mg/kg was administered orally to dogs and blood samples collected for measurements of clot strength and clot lysis (Brown et al., 2016). In that study, administration of aminocaproic acid inhibited fibrinolysis at all doses tested. The 100 mg/kg dose was more effective in dogs than 20 mg/kg, and it was concluded that 100 mg/kg oral every 6 hours is recommended for patients with hyperfibrinolysis. On the other hand, a case study on the use of aminocaproic acid in 122 dogs with potential bleeding disorders used the lower dose of 18 mg/kg (average dose) and examined the need for red blood cell transfusions. This clinical study could not reach any conclusions regarding efficacy. The drug dose was not associated with improvements in packed cell volume. As expected, the most common adverse effect in people is thrombosis formation during treatment.

The other antifibrinolytic agent used is tranexamic acid. It is an analog of aminocaproic acid and has the same properties and used for the same indications. Like aminocaproic acid, concentrations needed to completely inhibit fibrinolysis in canine plasma after induction of hyperfibrinolysis were determined by Fletcher et al. (2014). It is available (Cyklokapron®, Lysteda®) as oral 500 mg tablets and 100 mg/L for IV infusion. Optimum doses have not been evaluated for animals, but in surgeries associated with bleeding in people, a dose of 100 mg/kg IV after induction of anesthesia has been used (Myles et al., 2017). The adverse effects of thrombosis formation is similar to the risks with aminocaproic acid. An additional adverse effect observed in people is an association between administration of tranexamic acid and an increased risk of neurological events, including seizures.

Another drug, aprotinin (Transylol®) is a kallikrein or protease enzyme inhibitor. It was removed from the market in 2007 because of concerns about safety.

Hypothalamic and Pituitary Hormones

Srujana Rayalam, Margarethe Hoenig, and Duncan C. Ferguson

Introduction

The hypothalamus and pituitary control the function of the thyroid, adrenal glands, and gonads. Neurons and endocrine gland cells share the characteristic of being able to secrete chemical mediators and being electrically excitable. Chemical messengers can be secreted as a neurotransmitter or as a hormone. The neuroendocrine systems consist of clusters of peptide- and monoamine-secreting cells in the anterior and middle portions of the ventral hypothalamus. Their fibers project via nerve fibers to terminals in the outer layer of the median eminence. The capillary plexus of the median eminence is proximate to the nerve terminals of the periventricular nucleus (PVN) hypothalamic neurons, which make corticotropin-releasing hormone (CRH), thyrotropin-releasing hormone (TRH), and somatostatin (growth hormone inhibitory hormone, GHIH); arcuate hypothalamic nucleus neurons make gonadotropic hormone–releasing hormone (GnRH), growth hormone–releasing hormone (GHRH), and the prolactin-inhibiting neurotransmitter dopamine. The concentrations of the releasing and inhibitory hormones in the median eminence are 10 to 100 times as great as in other parts of the hypothalamus because they are stored in the nerve terminals (Cone et al., 2003; Rijnberk, 1996). The process of neurosecretion is characteristic of the hypothalamic nuclei, which release hormones into the portal vessels mediating the release of the anterior pituitary hormones such as growth hormone (GH), prolactin (PRL), thyrotropin (TSH), follicle-stimulating hormone (FSH), luteinizing hormone (LH), and the pro-opiomelanocortin (POMC)-derived peptides adrenocorticotropin hormone (ACTH), β-lipotropin (β-LPH), α-melanotropin (α-MSH), and the opioid β-endorphin (β-END). For each of the anterior lobe hormone systems (ACTH, LH, FSH, TSH, GH, and PRL), there is a closed-loop feedback system. Anterior lobe hormone and hypophysiotropic hormone secretions are suppressed by free (unbound) concentrations of hormones secreted by the respective end-organs, that is the thyroid, gonadal, and adrenal glands. Some hormones like PRL regulate their own secretion by inhibition via short-loop feedback on the hypothalamus. The somatotropes account for 50% or more of the anterior pituitary lobe cells, while other types of anterior lobe cells account for between 5 and 15% of the gland (Rijnberk, 1996). Table 26.1 outlines the location of neuroendocrine substances in the nervous system and endocrine organs. Tables 26.2, 26.3, and 26.4 show the key features of the structure and function of the hypothalamic regulatory and pituitary hormones. Many of these peptides find their clinical use as agents for diagnostic tests of pituitary or endocrine end-organ function. Therefore, the related hypothalamic and anterior pituitary hormones will be discussed concomitantly.

The magnocellular neurons in the supraoptic nucleus (SON) and PVN of the hypothalamus terminate in the posterior pituitary lobe and secrete vasopressin (antidiuretic hormone; ADH) and oxytocin into the circulation. Figure 26.1 outlines the hypothalamic pituitary endocrine system.

Anterior Pituitary and Associated Regulatory Hormones

The pituitary hormones can be classified into three general categories: ACTH-LPH, glycoproteins (LH, FSH, and TSH), and somatomammotropins (GH, PRL) (see Table 26.3).

Corticotropin and Related Peptides

Corticotropin-Releasing Hormone

Corticotropin-releasing hormone (CRH)-secreting neurons are found in the paraventricular nuclei, and their nerve endings terminate in external layers of the median eminence. CRH is synthesized as part of a prohormone of 196 amino acids in length and undergoes enzymatic modification to an amidated form of a 41-amino-acid peptide, which is identical in man, dog, rat, and horse

(Mol et al., 1994). CRH stimulates synthesis and secretion of POMC and ACTH by pituitary corticotrophs. Two major CRH receptor subtypes, CRH-R1 and CRH-R2, and a nonmembrane-associated CRH binding protein, have been identified (Hauger et al., 2003). Both the receptors belong to the G protein–coupled receptor superfamily, and are linked to adenylate cyclase. The CRH-R1 is the major subtype in the pituitary corticotroph, and it mediates the stimulatory actions of CRH on ACTH secretion through both the adenylate cyclase and calcium–calmodulin signal transduction systems (Klonoff and Karam, 1992; Tyrell et al., 1994). In addition, CRH and its receptors act outside the hypothalamic–pituitary–adrenal axis and maintain both acute and chronic synaptic stability to deal with daily or lifelong stressors (Orozco-Cabal et al., 2006). CRH neurons integrate inputs from physiological stressors such as osmotic challenge, hypoxia, and blood volume loss, and neurogenic stress such as fear and restraint. Chemical inputs to these neurons include inhibitory effects

Table 26.2 Hypothalamic regulatory hormones. See text for explanation of abbreviations.

Hormone	Action	Structure	Precursor	Target organ
TRH	Elevates TSH, PRL	Blocked tripeptide (pGlu-His-Pro-NH2)	29-kDa precursor containing five copies of TRH	Pituitary thyrotrope
GnRH	Elevates LH, FSH	Blocked decapeptide (pGlu…Gly-NH2)	Amino terminus of 90 amino acid precursor	Pituitary gonadotrope
Somatostatin	Decreases GH	14 Amino acid peptide with disulfide bond between residues 3 and 14	Carboxy- terminus of 92 amino acid precursor	Pituitary somatrotroph
CRH	Elevates ACTH	41 Amino acid peptide with amidated carbo xy-terminus	Carboxy- terminus of 190 amino acid precursor	Pituitary corticotroph
GHRH	Elevate GH	44 Amino acid peptide with amidated carbo xy terminus	Residues 32–75 from a 107 amino acid pre cursor	Pituitary somatotroph
Dopamine	Decreases PRL Increase GHRH or GH Decrease CRH or ACTH	Catechol		Pituitary lactotroph, somatotroph, corticotroph

Table 26.3 Anterior pituitary hormones. See text for explanation of abbreviations. *Source:* Adapted from Tyrell et al., 1994.

Hormone	Molecular weight	Amino acids	Other
I. ACTH-LPH			
ACTH	4,500	39	
β-LPH	11,200	91	Derived from POMC
β-END	4,000	31	
II. Glycoprotein			
LH	29,000	α subunit: 89 β subunit: 115	α subunits are identical within a species; β subunits contributes biological specificity
FSH	29,000	α subunit: 89 β subunit: 115	
TSH	28,000	α subunit: 89 β subunit: 112	
III. Somatomammotropins			
GH	21,500	191	Common ancestral hormone
PRL	21,500	198	

Table 26.4 Hormones of the hypothalamus and the pituitary gland. See text for explanation of abbreviations.

Hormone	Site of action (target organ)	Biologic activity
Hypothalamus		
Gonadotropin-releasing hormone	Anterior pituitary (AP)	Release LH and SH
Thyrotropin-releasing hormone	AP	Release TSH
Corticotrophin-releasing hormone	AP	Release ACTH
Somatotropin-releasing hormone	AP	Release somatotropin
Somatotropin-inhibitory hormone	AP	Inhibit somatotropin output
Prolactin-inhibitory hormone	AP	Inhibit prolactin output
Prolactin-releasing hormone	AP	Release prolactin
Adenohypophysis		
Par distalis (anterior lobe)		
Somatotropin (growth hormone)	General soma	Body growth (bone, muscle, organs), protein synthesis, carbohydrate metabolism, regulation of renal functions (glomerular filtration rate) and water metabolism; increases cell permeability to amino acids; favors lactation
Adenocorticotropin hormone (ACTH, corticotropin)	Adrenal cortex	Maintenance of structural integrity of adrenal cortex, regulation of glucocorticoid secretion by zona fasciculate
Thyroid-stimulating hormone (TSH, thyrotropin)	Thyroid	Maintenance of normal structure and function of the thyroid gland; production of thyroxin and analogs
Prolactin (lactogenic hormone)	Mammary gland	Possibly favors lactation

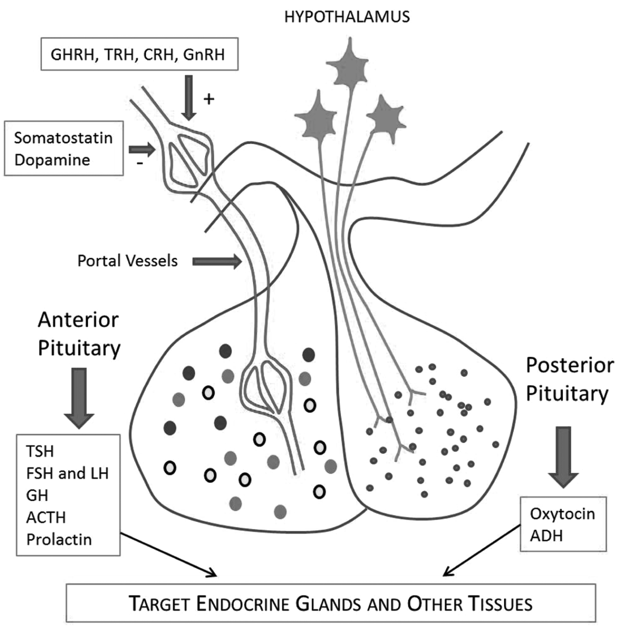

Figure 26.1 The hypothalamic pituitary endocrine system. Hypothalamic hormones regulate the release of anterior pituitary hormones. All the anterior pituitary hormones except for GH and prolactin act on their target endocrine glands to stimulate the production of hormones. GH has no single endocrine gland, instead it acts on liver and several other tissues. Prolactin and posterior pituitary hormones, ADH, and oxytocin act directly on target tissues like mammary gland, kidney, and uterus. ACTH, adrenocorticotropin hormone; ADH, antidiuretic hormones; CRH, corticotropin-releasing hormone, FSH, follicle stimulating hormones; GH, growth hormones, GHRH, growth hormone releasing hormone, GnRH, gonadotropin releasing hormone; LH, luteinizing hormone; TRH, thyrotropin releasing hormone, TSH, thyroid. stimulating hormone.

of γ-aminobutyric acid (GABA) and, of course, negative feedback from glucocorticoids. Stimulatory effects are provided by glutamate, serotonin, and cytokines such as interleukin (IL)-1, IL-2, IL-6, and tumor necrosis factor-α (TNF-α). Intravenous CRH, acting via CRH-R2β receptors on the cardiac atria and ventricles, results in hypotension and bradycardia (Cone et al., 2003). CRH has also been identified as an anxiogenic and anorexogenic factor, prompting research into CRH antagonists as both mood altering and appetite-stimulating drugs (Cone et al., 2003). A CRH inhibitory factor has been postulated, and atrial natriuretic peptide, activins, and inhibins are considered as candidate peptides (Engler et al., 1999).

Adrenocorticotropin

Biosynthesis

Adrenocorticotropin (ACTH) is a 39-amino-acid peptide hormone (MW 4,500), which is one of several products from the metabolism of the 267-amino-acid precursor molecule POMC (MW 28,500) (Figure 26.2). Between species, there is significant sequence homology in the ACTH amino acid structure. Canine ACTH differs by only one C-terminal amino acid from ACTH of other species (Mol et al., 1991). The other fragments of POMC with biological activity include β-lipotropin (β-LPH), α-melanocyte–stimulating hormone (α-MSH), β-MSH, and the opioid β–endorphin, as well as the N-terminal fragment (Figure 26.2). ACTH is metabolized to ACTH_{1-13}, which is identical to α-MSH, and corticotropin-like intermediate lobe

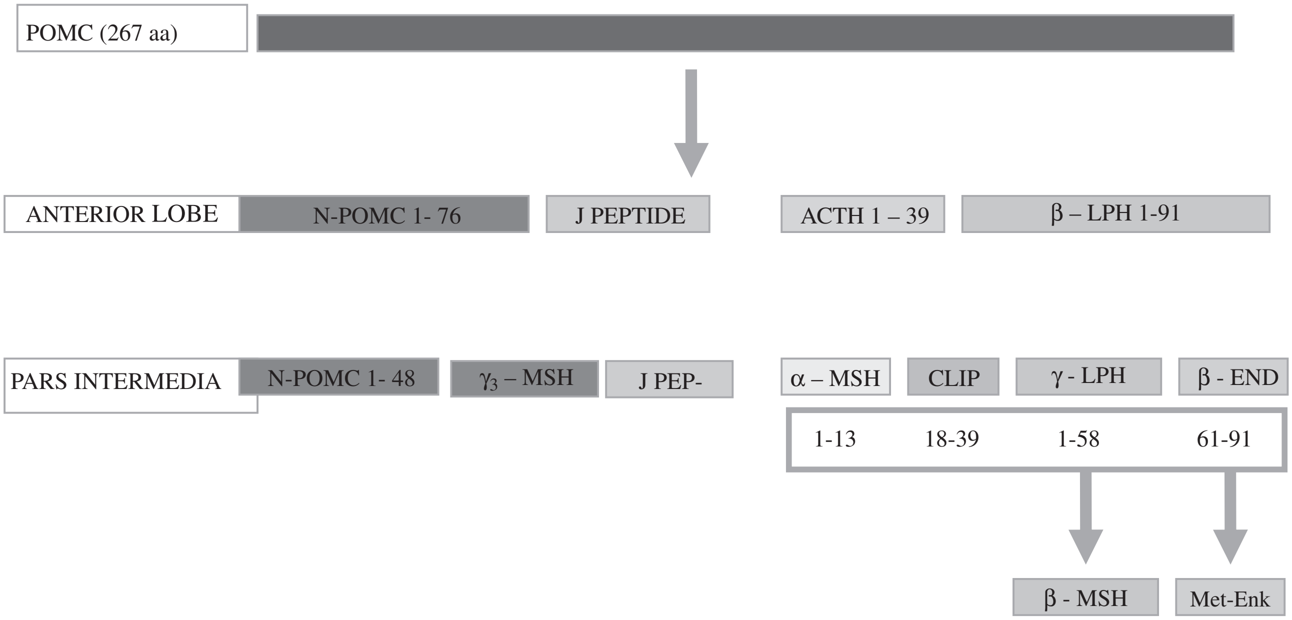

Figure 26.2 Relationships of pro-opiomelanocortin (POMC) derived peptides. Following synthesis in the anterior or intermediate lobe of the pituitary, POMC is cleaved to form adrenocorticotropin (ACTH) and β-lipotropin (β-LPH). ACTH further degrades, particularly in the intermediate lobe, to α-melanocyte stimulating factor (α-MSH) and corticotropin-like intermediate lobe peptide (CLIP). β-LPH is cleaved to produce γ-LPH and the endogenous opiate β-endorphin (β-END). γ-LPH is cleaved to produce β-MSH and β-endorphin is further processed to produce another opioid met-enkephalin (Met-Enk).

peptide (CLIP), which represents ACTH$_{18–39}$. These fragments are observed in species with developed intermediate lobes, such as the rat and horse, as well as fish, reptiles, and amphibians. β-LPH is secreted in equimolar amounts to ACTH. The 91 amino acids of β-LPH include the amino acid structure for β-MSH (41–58), γ-LPH (1–58), and β-END (61–91). The first (N-terminal) 23 amino acids of ACTH, which are identical in humans, cattle, pigs, and sheep, produce all of its biological effects (Klonoff and Karam, 1992; Tyrell et al., 1994). The sequence of the remaining amino acids varies among species (Chastain and Ganjam, 1986). MSH causes pigment granules in melanocytes to disperse so that skin will darken. Although genetic factors associated with skin color are more important in the higher vertebrates, in mammals, MSH may cause transiently increased pigment synthesis. In addition to the pigmentary action, α-MSH exhibits cytoprotective activity against UV-induced apoptosis and DNA damage in cutaneous tissue (Böhm et al., 2006).

Structure

ACTH is a peptide that contains 39 amino acids in a straight chain molecule in sheep, pig, cow, and human. The first 24 and last seven amino acids are identical in these species and there are minor differences in amino acids 25 through 32 (Figure 26.3). The amino acid sequence of canine β-END differs from the human sequence by four amino acids (Young and Kemppainen, 1994). The distribution of molecular forms of β-END in the canine intermediate lobe and anterior pituitary resembles most closely that in rats. In other species, such as sheep or horse, acetylated and shortened forms exist in substantial amounts. In all species studied to date, ACTH and related peptides are synthesized and cleaved from a common precursor molecule POMC. Posttranslational processing of POMC differs in the pars distalis and pars intermedia of the pituitary gland. In the pars distalis, POMC is processed to form ACTH, β-LPH, and some γ-LPH and β-END. In the pars intermedia, however, POMC is processed to ACTH and β-LPH; ACTH is then

further processed to α-MSH and CLIP, and β-LPH is further processed to β-MSH, β-END, and β-END metabolites. As a result, ACTH and β-LPH are intermediates to α-MSH and the opiate β-END. The pattern of POMC-derived peptide secretion from the pars intermedia has been characterized in rats, horses, pigs, sheep, dogs, and cats. The plasma POMC peptide concentrations found in cats is similar to that in rats, but is markedly different from that in dogs, in which the secretion of POMC peptides in the pars intermedia is normally low (Peterson et al., 1994b). N-POMC (1–77) promotes adrenocortical cell replication, and the growth-promoting actions may be a result of either direct action of N-POMC (1–77) at the fetal adrenal gland or a consequence of proteolytic cleavage of N-POMC (1–77) at the adrenal gland (Coulter et al., 2002).

Regulation of Secretion

β-LPH and β-endorphin are secreted in a pattern similar to ACTH, increasing in response to stress and paralleling ACTH in a variety of disease conditions. The regulation of ACTH is most directly influenced by the hypothalamic hormone CRH, which stimulates ACTH in a pulsatile fashion. Arginine-vasopressin (ADH) is also a potent stimulus for ACTH secretion (van Wijk et al., 1994). The pulsatility of ACTH release appears to occur in most species. Although a diurnal variation of cortisol exists in man, studies with sampling at 30-minute intervals for 48 hours have not confirmed a diurnal variation in ACTH in dogs or cats (Peterson et al., 1994c).

Four mechanisms have been identified to regulate ACTH secretion: (i) episodic secretion and possible diurnal variation, mediated by the CNS and hypothalamus; (ii) response to stress (cat much more sensitive than dog) mediated by the CNS and hypothalamus; (iii) feedback inhibition by cortisol at both the hypothalamus and pituitary; and (iv) immunological factors (IL-1, IL-6, TNF, etc.), which act at the hypothalamus to increase CRH (Rijnberk, 1996; Cone et al., 2003). Facilitatory and inhibitory pathways involving GABAergic, cholinergic, adrenergic, dopaminergic, and serotoninergic systems are all involved in hypothalamic regulation of ACTH and cortisol secretion. Drugs manipulating these systems have been utilized to manage pituitary-dependent hyperadrenocorticism in the dog and horse. Ergot alkaloids (dopamine agonists) and serotonin antagonists (cyproheptadine) have been utilized to manipulate ACTH release without much clinical success. The monoamine oxidase B inhibitor L-deprenyl was developed and approved by the FDA for use in dogs with pituitary-dependent hyperadrenocorticism (Bruyette et al., 1997a, 1997b). In theory, reduction of the rate of dopamine degradation by this class of drugs should increase dopamine and suppress ACTH secretion (Klonoff and Karam, 1992). Subsequent studies have been less enthusiastic about this drug as the sole treatment for canine pituitary-dependent hyperadrenocorticism (Reusch et al., 1999; Braddock et al., 2004).

Many factors stimulate ACTH secretion: pain, trauma, hypoxia, hypoglycemia, surgery, cold, pyrogens, and vasopressin (at least in man). CRH is often used pharmacologically to release ACTH from the pars distalis, and the drug haloperidol can be used to stimulate pars intermedia secretion with pars distalis effects being removed by dexamethasone. In cultured canine anterior pituitary cells, it appears that CRH stimulates ACTH secretion, but arginine vasopressin, oxytocin, and angiotensin II do not (Kemppainen et al., 1992).

Negative-Feedback Systems

Exogenous corticosteroids suppress the ACTH response to stress. Negative feedback of cortisol occurs via both the hypothalamic and pituitary. Feedback occurs in three ways:

1) Fast feedback is sensitive to the rate of change in cortisol and probably occurs via a nonnuclear receptor.
2) Slow feedback that is sensitive to the cortisol concentration in plasma. This feedback loop is tested by the low-dose dexamethasone suppression test.
3) Short-loop feedback by ACTH on the release of CRH by neurons in the hypothalamus and corticotrope receptors in the corticotropic cells of the anterior pituitary. The feedback is mediated through a type I mineralocorticoid-preferring receptor (MR) and a type II glucocorticoid-preferring receptor (GR). The highest level of GR in the dog brain is found in the septohippocampal complex and the anterior lobe of the pituitary (Reul et al., 1990; Keller-Wood, 1990; Klonoff and Karam, 1992; Tyrell et al., 1994).

Function

ACTH stimulates the secretion of glucocorticoids, mineralocorticoids, and adrenal androgens by increasing the activity of cholesterol desmolase, the enzyme that is rate limiting for steroid production and converts cholesterol to pregnenolone. ACTH also stimulates adrenal hypertrophy and hyperplasia. Steroids are not stored in the adrenal cortex, but they are immediately released upon stimulation of the zona fasciculata. ACTH causes growth of both the zona fasciculata and glomerulosa. The biological activity is conveyed by the amino terminal end of the molecule. ACTH stimulates adrenocortical growth and steroidogenesis by increasing cellular cAMP (Tyrell et al., 1994).

LPH induces lipolysis in adipocytes of some species, but its function is largely unknown other than serving as a precursor peptide for β-END, which is an endogenous opiate (Klonoff and Karam, 1992; Kuret and

Murad, 1990). However, a comparative study of the central effects of specific POMC-derived melanocortin peptides on food intake and body weight indicated that most of the POMC-derived melanopeptides, including γ-LPH, reduced food intake in POMC-null mice (Tung et al., 2006).

Diagnostic Uses of CRH and ACTH

The most important applications of CRH and ACTH are as a diagnostic agent to test adrenocorticotroph and adrenal functional reserve.

CRH Stimulation Test

The CRH stimulation test is used mainly as a research tool to assess pituitary ACTH secretory capacity. In animals administered exogenous glucocorticoids, the ACTH and cortisol response to CRH is diminished. In dogs and cats, ovine CRH is administered at 1 μg/kg intravenously and plasma is sampled for ACTH measurement at 0 and 0.5 hours for peak effect (Table 26.5). Other sampling times have been employed in research reports (Crager et al., 1994; Moore and Hoenig, 1992; Peterson et al., 1994b, 1994c; Scott-Moncrieff et al., 2003). Dogs with primary adrenal insufficiency have high basal plasma immunoreactive ACTH concentrations and show exaggerated responses to CRH, whereas dogs with secondary adrenal insufficiency showed undetectable basal plasma concentrations of immunoreactive ACTH that did not increase after stimulation with CRH (Peterson et al., 1992). On the other hand, studies of normal dogs and dogs with pituitary-dependent hyperadrenocorticism have shown that ACTH secretion is less sensitive to CRH than with lysine vasopressin (LVP). It was found that adrenocortical tumors develop an aberrant sensitivity to LVP, with adrenal tissue appearing to directly respond to LVP (van Wijk et al., 1994).

Preparations of ACTH

Synthetic human $ACTH_{1-24}$ is called cosyntropin (Cortrosyn®, Amphastar Pharmaceuticals). Repositol ACTH gel from animal (porcine) sources is no longer available commercially. However, when comparing dosage protocols, 1 unit of porcine ACTH is approximately equal to 10 μg of cosyntropin. Synthetic ACTH is well absorbed by the IM route. The biological half-life of all forms of ACTH is 10 to 20 minutes and has an effect on the adrenal cortex for 12 to 48 hours. Generic cosyntropin is also available from Sandoz, Inc and a study has indicated that injection of generic cosyntropin stimulates adrenocortical secretion to an equivalent degree, as compared with Cortrosyn in dogs (Cohen and Feldman, 2012).

ACTH Stimulation Test

The main use of ACTH is the differential diagnosis of adrenocortical hyperplasia from adrenocortical neoplasia (primary) in dogs, cats, and horses (Table 26.6), and in the definitive diagnosis of primary adrenal hypofunction. ACTH is well absorbed following IM injection. Following injection of aqueous synthetic ACTH, largely because of the short half-life of ACTH, plasma cortisol concentrations peak at 30 to 90 minutes. Therefore, most sampling protocols with aqueous ACTH in dogs recommend sampling times at 1 hour after administration for a peak effect. The administration of 250 μg synthetic ACTH to dogs resulted in similar cortisol patterns, whether the dose was given IV or IM, despite the fact that there were much higher peak ACTH concentrations with the intravenous dose. Additional studies further confirmed that in healthy dogs and dogs with hyperadrenocorticism, administration of cosyntropin, a synthetic derivative of ACTH, at a dose of 5 μg/kg, IV or IM, not only resulted in equivalent adrenal gland stimulation (Behrend et al., 2006) but is also effective for diagnosing hypoadrenocorticism in dogs (Lathan et al., 2008). The peak cortisol concentration was at 60–90 minutes (Hansen et al., 1994). Interestingly, the increase in cortisol concentrations from 1–2 hours post-ACTH injection at a dose of 250 μg/animal IV in adult Cocker Spaniel dogs, was significantly higher in females than males (Pessina et al., 2009). However, in cats, the intravenous dose of synthetic ACTH appeared to provide a greater response compared to the IM dosage but the peak cortisol response is somewhat variable and post-ACTH samples at 45 and 60 minutes are recommended (Peterson et al., 1994b, 1994c).

Evaluation of Partial or Relative Adrenal Insufficiency in Foals

Studies have sought to evaluate the dose-dependency of the cortisol response to ACTH as an index of adrenal insufficiency in systemically ill foals. A randomized crossover study of intravenous ACTH (Cosyntropin) in healthy foals at 3–4 days of age demonstrated that while 1 μg of ACTH had not yet reached a threshold dose, 10 μg resulted in a peak cortisol at 30 minutes returning to baseline by 90 minutes, while 100 and 250 μg both elicited a peak cortisol response at 90 minutes (Hart et al., 2007). In contrast, administration of ACTH (Cosyntropin) at a dose of 0.1 μg/kg resulted in maximum adrenal stimulation, with peak cortisol concentration 30 minutes after ACTH administration in healthy adult horses.

Melatonin

The pineal gland consists of photoreceptive cells, which have functional significance in fish and amphibians, but the pinealocytes function mainly as secretory cells in higher vertebrates. In vertebrates, light–dark cycle information is related to the pineal via indirect multisynaptic input, crucial to the control of biological rhythmicity. The retina provides light information to the suprachiasmatic nucleus (SCN) of the hypothalamus via the retinohypothalamic tract. The SCN provides input to the PVN via intrahypothalamic projections. The PVN then innervates sympathetic preganglionic neurons in the intermediolateral neurons in the cranial cervical ganglion, which then provides noradrenergic input to the pineal gland.

In mammals, the pinealocytes are the source of melatonin. Melatonin is synthesized from the amino acid tryptophan, via serotonin. Melatonin synthesis is tightly controlled in a circadian manner and is entrained to the light–dark cycle with highest melatonin concentrations during dark periods. The signal transduction associated with these changes in melatonin secretion is as follows: the absence of light leads to norepinephrine release from sympathetic nerve terminals that act upon G-protein coupled β-adrenergic receptors, which increase adenylate cyclase activity. Cyclic AMP–response element in the promoter region for *N*-acetyltransferase is the rate-limiting step for melatonin synthesis. Melatonin then acts on a family of G-protein coupled receptors (Mel1a, Mel1b, and Mel1c), depending upon the species of animal. Melatonin thereby inhibits the activity of neurons in the SCN, considered the circadian pacemaker of the mammalian brain. This regulation is key to entraining reproductive patterns in species such as the sheep and horse.

Melatonin can be used as therapy for alopecia X in dogs. Alopecia X is a controversially defined condition (or conditions) associated with hair loss in dogs, which cannot be attributed to known endocrinopathies such as hypothyroidism and hyperadrenocorticism. One proposed treatment is melatonin at a dose of 3–6 mg/dog once or twice a day (Frank et al., 2004). Response rate may vary greatly depending on the severity and chronicity of the problem, and recurrence is not uncommon despite therapy.

Glycoprotein Hormones and Associated Releasing Hormones

Only the thyroid-related peptides thyrotropin-releasing hormone (TRH) and thyroid stimulating hormone (TSH) will be discussed in this chapter. Gonadotropin-releasing hormone (GnRH), luteinizing hormone (LH), placental chorionic gonadotropin (HCG), and pregnant mare serum gonatropin (PMSG) are discussed in Chapter 27 on reproductive drugs.

Thyrotropin-Releasing Hormone

Thyrotropin-releasing hormone (TRH) is a tripeptide: PyroGlu-His-Pro-NH_2. Neurons secreting TRH are located in the medial portion of the paraventricular nuclei and their axons terminate in medial portions of the external lamina of medial eminence. TRH is present extensively in the brain outside of the classic "thyrotropic area" of the hypothalamus. An intact amide and the cyclized glutamic acid terminus are essential for activity. TRH is synthesized as a large 242-amino-acid precursor, which contains five repeating sequences in the rat and six in the human called *preprothyrotropin-releasing hormone* (preproTRH) (Jackson, 1982; Lechan et al., 1984; Yamada et al., 1990). The prohormone undergoes extensive posttranslational processing, including enzymatic cleavage, cyclization of NH_2-terminal glutamic acid, and exchange of an amide for the COOH-terminal glycine. TRH binds to specific receptors on the plasma membrane of the pituitary cell (Halpern and Hinkle, 1981). TRH activates membrane adenylate cyclase with the formation of cAMP and the increase in cAMP stimulates TSH secretion. However, cAMP may not increase under all conditions of TRH-induced TSH release, and increased intracellular cAMP is not always associated with an increase in TSH secretion. There is growing evidence that the TRH-induced increase in cAMP concentrations may be a secondary event. It is now widely accepted that TRH action is mediated mainly through activation of phospholipase C. It causes hydrolysis of phosphatidyl-inositol-4,5-biphosphate (PIP_2) into inositol-1,4,5-triphosphate (IP_3) and 1,2-diacylglycerol (DAG). DAG then activates protein kinase C. Continuous exposure of TRH receptors to TRH causes an increase in

IP_3 concentration that peaks within 10 seconds and falls within 1 minute, indicating the rapid desensitization of the TRH response (Yu and Hinkle, 1997). The binding of β-arrestins is shown to be critical for desensitization (Jones and Hinkle, 2005). TRH induces an immediate and rapid increase in intracellular free calcium, which decays rapidly, followed by an extended plateau of elevated calcium. The first phase reflects increased release of intracellular calcium stores, whereas the second phase represents calcium influx. This biphasic action correlates with electrical charges, induction of Ca^{2+} fluxes, and secretory activity in pituitary cells (Geras and Gershengorn, 1981; Gershengorn et al., 1980; Tashjian et al., 1987; Vale et al., 1977; Winiger and Schlegel, 1988).

TRH Stimulation Test

Diagnosing hypothyroidism in the dog: The TRH stimulation test, as it is used in the diagnosis of human pituitary and thyroid disease, is designed to evaluate the pituitary's responsiveness to TRH as manifested by the change in serum TSH concentration. In primary thyroid gland failure, the pituitary response to TRH is increased, and, in hyperthyroidism, it is decreased.

TRH has been most commonly applied instead of exogenous TSH to evaluate thyroid functional reserve by the increment in serum thyroxine (T_4) concentrations. Figure 26.4 shows the theoretical response of serum T_4 to TRH and TSH administration. In theory, the administration of TRH should lead to an increase in T_4 only if the pituitary–thyroid axis is intact (Figure 26.4). Therefore, responsiveness to TRH should be observed only in tertiary (hypothalamic) thyroid insufficiency, a condition not yet documented in the dog (Ferguson, 1984, 1994, 2007). Since the availability of the canine TSH assay in 1997, more has been learned about regulation of TSH secretion. In human patients, an increased response of TSH to TRH generally demonstrated an enhanced response in early or mild primary hypothyroidism. However, evaluation of TRH-stimulated TSH responsiveness has not proved to be of much more diagnostic value than baseline canine TSH concentrations (Scott-Moncrieff et al., 1998; Hoenig and Ferguson, 1997; Ferguson, 2007). Furthermore, chronic hypothyroidism

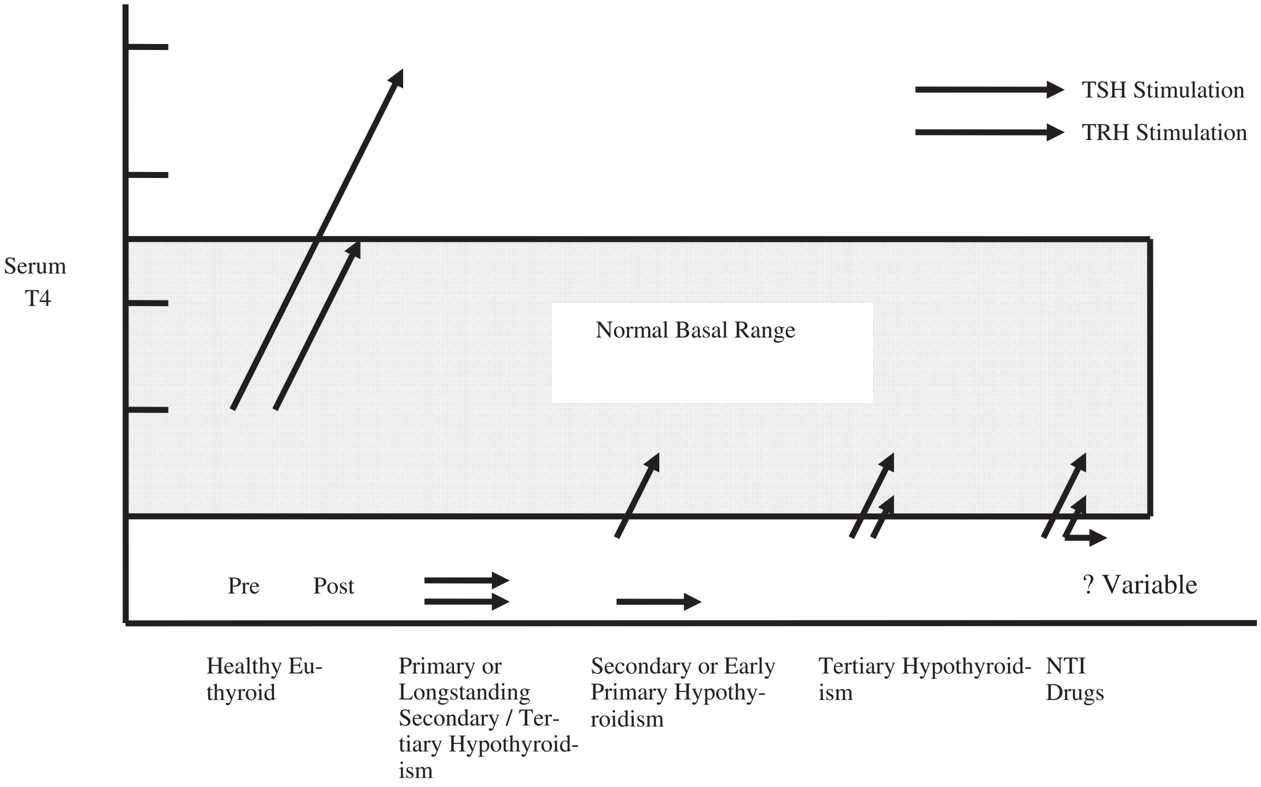

Figure 26.4 Diagnostic classifications based upon thyrotropin-releasing hormone (TRH) and thyrotropin (TSH) stimulation tests. The arrows represent in a stylized fashion the classical response of serum thyroxine (T_4) concentrations to optimal doses of TRH and TSH. The actual magnitude of response will, in part, be determined by the dosage of TRH and TSH and the time of serum sampling post-TRH or post-TSH. The shaded area represents the normal baseline serum T_4 concentrations. Note the lower relative response to even maximal dosages of TRH compared to TSH. The left arrow in each pair of arrows (darker arrow) represents the response to TSH and the right arrow (lighter) represents the response to TRH. NTI, nonthyroidal illness. *Source:* Peterson and Ferguson, 1989.

Table 26.7 Protocols for TRH stimulation test. *Sources:* Ferguson, 1984, 1994; Lothrop and Nolan, 1986; Lothrop et al., 1984; Peterson and Ferguson, 1989; Peterson et al., 1994a, 1994c.

	Dose	Route	Sampling times (hour)
Dogs	200 µg	IV	0, 4
Cats	100 µg/kg	IV	0, 4
Horse	1000 µg	IV	0, 4

Preparations used are Relefact TRH® (Hoechst-Roussel); Thypinone® (Abbott Diagnostic); TRH (Peninsula Laboratories).

has been shown to be associated with a rise then a fall in baseline TSH. This observation may contribute to as much as 25–40% of dogs with primary hypothyroidism having a normal, and not elevated, TSH concentration. It is not yet clear whether this phenomenon is associated with a desensitization toward negative feedback; however, TRH-stimulated increments in TSH seem to decline with time (Diaz-Espineira et al., 2008).

A variety of TRH dosages have been proposed for use in the dog. In general, regardless of the species, increasing the TRH or TSH dose increases the duration of the serum T_4 response. In the dog, side effects were more significant at dosages greater than 100 µg/kg; salivation, urination, defecation, vomition, miosis, tachycardia, and tachypnea were observed (Table 26.7). The recommended protocol for the TRH stimulation test is the administration of 100 µg/kg TRH intravenously with the collection of serum for T_4 measurement at 0 and 6 hours post-TRH if serum T_4 is measured, and at 0 and 30 minutes if serum TSH is measured. Using this protocol in normal dogs, at least a 50% increase in serum T_4 was observed in 90% of dogs and all dogs had an increase of at least 0.5 µg/dl (6.4 nmol/l) above baseline (Figure 26.4). With the lower dose of 200 µg TRH per dog, serum T_4 was shown to be maximal 4 hours after TRH administration. Because of the small increments following TRH, the successful application of the TRH stimulation test requires the use of a T_4 assay with extremely good internal reproducibility or preferentially, measurement of canine TSH.

Diagnosing hypothyroidism in the horse: TRH has been evaluated in horses as an alternative for establishing the pituitary thyrotrope and thyroid functional reserve. Intravenous administration of 1,000 µg of TRH increases serum concentrations of T_4 and T_3 peaking at 4 hours post-TRH (Table 26.7) (Lothrop and Nolan, 1986). TRH has also been used at a dose of 2,000 µg IV with samples at 0, 30, and 90 minutes, to evaluate possible pituitary disease in the horse. However, there was no increase in progesterone, 17-hydroxyprogesterone, androstenedione, cortisol, aldosterone, testosterone, or estradiol, raising the question about the validity of TRH for evaluation of adrenal dysfunction in the horse (Fecteau et al., 2005).

Diagnosing mild hyperthyroidism in the cat: In some instances, thyroid hormone concentrations (T_4 and T_3) are normal, are borderline, or even fluctuate into and out of the normal range in cats with mild hyperthyroidism. The TRH stimulation has been studied as a test of thyroid autonomy. In euthyroidism, the thyroid gland of the cat responds significantly to intravenous TRH, but the response in the hyperthyroid cat is considerably less, implying that thyroid function is not under the influence of endogenous TSH. The dosage of 100 µg/kg TRH administered intravenously is followed by serum sampling at 4 hours after injection. Serum T_4 concentrations increased by >50% in all normal cats and cats with nonthyroidal disease, whereas only 11% of hyperthyroid cats showed a 50% increase in serum T_4 concentration after TRH administration. Although case-controlled studies have established relative specificity, others have questioned the specificity the TRH stimulation test results in the presence of nonthyroidal illness (Peterson et al., 1994a, 2001). Adverse side effects in the cat associated with administration of TRH were common and included transient vomiting, salivation, tachypnea, and defecation. As a diagnostic test, the TRH stimulation test compares favorably with the T_3 suppression test while requiring less time, and it is more convenient to perform (Peterson et al., 1994a, 1994c). The biological activity of freshly reconstituted TRH is maintained when frozen at −20°C for 1 to 5 weeks (Rosychuk et al., 1988).

Thyrotropin

Chemistry

Thyroid stimulating hormone (TSH) is a glycoprotein of MW 28,000 that is synthesized by thyrotrope cells of the anterior pituitary (Table 26.3). It is chemically related to the family of glycoproteins, including the pituitary gonadotropins LH, FSH, and placental chorionic gonadotropin (CG). Each of these hormones contains two noncovalently linked dissimilar polypeptide chains, alpha and beta.

LH, FSH, and TSH all share similarities in tertiary structure conferred by the evolutionary preservation of cysteine residues, particularly those involved in the “cysteine knot” motif identified by crystallographic information. Furthermore, sites of *N*-glycosylation also appear to be preserved during evolution. As described below, glycoproteins contribute to the tertiary structure as well as the functional and immunogenic characteristics of the dimers (Zerfaoui and Ronin, 1996).

Alpha and Beta Subunits

TSH is a heterodimer composed of two noncovalently bound subunits, alpha and beta. The subunits are synthesized as separate peptides from distinct mRNAs (Vamvakopoulos and Kourides, 1979). The alpha subunit is common to all three hormones, but the beta subunit is unique for each hormone and confers biological specificity. For all four glycoproteins within each species, the amino acid sequence of the alpha subunit is common. However, the carbohydrate structure may vary. Microheterogeneity of the carbohydrate constituents of the individual hormones causes heterogeneity in receptor affinity, biological potency, and metabolic clearance (Pierce and Parson, 1981; Wondisford et al., 1988).

The alpha subunits are approximately 20 to 22 kD, have 92 to 96 amino acid residues, and contain two N-linked carbohydrate groups. The human, cow, mouse, dog, cat, and rat alpha subunit genes are similar (Yang et al., 2000b; Rayalam et al., 2006a, 2006b). All species have a single mRNA species that is between 730 and 800 bases long. The mRNA encodes the precursor of the alpha subunit and a leader sequence of an average of 24 amino acids.

The TSH beta subunit is approximately 18 kD, and consists of approximately 110–113 amino acids and contains one N-linked complex carbohydrate (Green and Baenziger, 1988). TSH, like LH, contains sulfate groups that terminate certain chains; such sulfation is found only to a small extent in FSH and not at all in CG. The genes for beta subunit of TSH of mouse, cow, human, dog, and horse have been cloned and recombinant canine TSH (Yang et al., 2000a, 2000b) and feline TSH (Rayalam et al., 2006a, 2006b) have been expressed in vitro. Each mRNA is approximately 700 bases in length with minor variations. The TSH beta mRNA encodes the precursor TSH beta subunit with a 20–amino-acid leader sequence and a 117– or 118–amino-acid coding region.

The alpha subunit peptide is more abundant than the unique beta subunit of peptides. Free serum alpha subunits are secreted and are present in equivalent concentrations to combined concentration of TSH, LH, and FSH. Free serum beta subunit concentrations are lower, usually below the level of detectability. Overabundance of alpha subunit suggests that regulation of beta subunit synthesis is the rate-limiting step in modulating the levels of TSH, LH, and FSH (McNeilly et al., 2003; Taylor and Weintraub, 1985).

Action

TSH binds to specific receptors on the thyroid plasma membrane. TSH receptors (TSHR) from dog, cat, pig, human, and rat have been completely cloned and species comparisons reveal a high degree of homology of more than 90%. The extracellular domain of the receptor contains 398 amino acids with five sites for N-linked glycosylation. The intracellular domain has 346 amino acids with seven putative transmembrane segments. The stimulatory guanine nucleotide regulatory protein binds to the third intracellular loop. The receptor has a glycoprotein component and a ganglioside, which may be involved in TSH activation of adenylate cyclase. TSHR is unique among glycoprotein hormone receptors in that some mature receptors on the cell surface are cleaved into two subunits (Rapoport et al., 1998). Only intact TSH binds to the receptor and the beta subunit does not possess biological activity (Chan et al., 1987; Field, 1975). Binding of TSH to its receptor activates adenylate cyclase and subsequent accumulation of cAMP, but is not dependent on the interaction of the TSH from that species with the receptor. This results in the stimulation and dissociation of the regulatory and catalytic subunits of cAMP-dependent protein kinase (protein kinase A) with subsequent phosphorylation of various cellular proteins resulting in an increase in thyrocyte iodide uptake, thyroid hormone organification, and thyroid hormone secretion. This cyclic AMP–mediated pathway appears to be important in both thyroid hormone secretion and thyroid glandular growth (Chayoth et al., 1985). Another important function of TSH in this context would be the up-regulation of sodium iodide symporter (NIS) in the thyroid cells. Several in vivo and in vitro studies showed that TSH stimulates not only iodide transport activity but also NIS gene and protein expression (Kogai et al., 1997, 2000; Saito et al., 1997).

The binding of TSH is also known to activate the phospholipase C signaling system. Activation of phospholipase C results in hydrolysis of PIP_2 with formation of DAG and IP_3. The former activates a Ca^{2+}-phospholipid–dependent protein kinase (protein kinase C) and the latter increases intracellular Ca^{2+} concentrations. The effect of TSH on phospholipase C is slower and requires larger amounts of the hormone than its activation of adenylate cyclase, suggesting a high-capacity and low-affinity TSH binding site. The physiological significance of activation of PIP_2 hydrolysis by TSH is not known, but is suspected to be involved in thyroid glandular proliferation (Chayoth et al., 1985; Taguchi and Field, 1988).

Preparations

Two bovine thyrotropin products have been available in the past. Availability of biochemically purified native TSH from bovine pituitary glands as a pharmaceutical has been drastically reduced following the introduction of human recombinant TSH and following the emergence of bovine spongiform encephalopathy. In addition, significantly higher endotoxin levels were detected in commercially available bTSH products, discouraging their use to prevent side effects (Schaefer et al., 2013). Nonetheless, investigators occasionally still use cell culture grade bTSH product for animal use. Although canine and feline recombinant TSH could successfully be synthesized, it is not commercially available (Yang et al., 2000a; Rayalam et al., 2006a). Regardless of the source, it is stored in a lyophilized form for reconstitution and parenteral administration. A study evaluated the effects of freezing reconstituted bovine TSH and demonstrated that bioactivity remained intact for at least 3 weeks at 4°C (Bruyette et al., 1987; Ferguson, 1994). Furthermore, the effect of storage conditions on the use of recombinant human thyrotropin (rhTSH) for TSH stimulation testing in dogs indicated that reconstituted rhTSH can be stored at 4°C for 4 weeks and at −20°C for 8 weeks without loss of biological activity (De Roover et al., 2006).

Thyrotropin Stimulation Test

The administration of exogenous bovine or human TSH followed by the measurement of serum T_4 and/or T_3 is a procedure still used occasionally to confirm the diagnosis of hypothyroidism, or loss of thyroid secretory reserve. Historically, it has been applied primarily in the dog, cat, and horse. The availability of immunoassays measuring endogenous canine TSH have reduced the practicality and need for this test. However, the TSH stimulation test continues to be considered a noninvasive test for confirming the reduced thyroid functional reserve associated with hypothyroidism.

Protocols for this test in the dog vary widely and are summarized in Table 26.8. Although the TSH dose and serum sampling times are often dictated by practical and economic considerations, increasing the TSH dose administered generally delays the time of the T_4 peak, and, up to a limit, results in a higher serum T_4 response and a plateau that is maintained for a longer period of time. The route of administration may be intravenous, intramuscular, or subcutaneous; however, the most consistent and rapid response is seen after intravenous dosing. For the dog, the suggested protocol is to draw a baseline blood sample for serum T_4 determination, and then administer 0.1 IU/kg TSH intravenously (maximum dose 5 units), followed by a blood sample at 4 or 6 hours post-TSH (Ferguson, 1984, 1994, 2007). Studies using 1 unit of bovine TSH (bTSH) per dog have indicated that the mean increase in serum T_4 and T_3 above baseline at 6 hours post-TSH was significantly lower following TSH at 1 IU than TSH at 5 IU but was not significantly different at 4 hours post-TSH for the two doses of TSH evaluated. Based on the criteria for adequate response to TSH, TSH at 1 IU led to classification of 35% of the dogs as having a decreased response to TSH at 4 hours and 35% at 6 hours. TSH at 5 IU resulted in no dogs having a decreased response at 4 hours and 1 dog in 20 (5%) at 6 hours (Beale et al., 1990).

Table 26.8 Protocols for thyrotropin-releasing hormone (TSH) stimulation test. Sources: Beale et al., 1990; Chen and Li, 1987; Ferguson, 1984,1994; Peterson and Ferguson, 1989; Sauvé and Paradis, 2000; Stegeman et al., 2003.

	Dose or dosage	Route	Sampling times (hours)
Dog	0.1 unit/kg (max. 5 units)	IV	0, 4
	1 unit/dog	IV	0, 4
	50 μg/dog[a]	IV	0, 4, 6
Cat	1 unit/kg	IV	0, 6
	1 unit/cat	IV	0, 4
	25–200 μg/cat[a]	IV	0, 6
Horse	5–10 units	IV	0, 4, 6

Preparation used was bovine TSH (Thytropar®; Rhone-Poulenc Rorer).
[a] Preparation used was recombinant hTSH (Thytropar®, Genzyme Corporation).
For older protocols in the dog, see Ferguson, 1984 for a review.

Pituitary-source preparations of TSH have been standardized according to bioactivity, which is reported as International Units (IU). Highly purified TSH approaches a biological specific activity of 12.5 IU activity/mg protein. A study compared the biological activity of recombinant human TSH (rhTSH) with bTSH in dogs, where bTSH was administered (1 unit corresponding to 500 μg in 0.5 ml of sterile water) intramuscularly and rhTSH was administered (75 μg in 0.5 ml sterile water) both intramuscularly and intravenously. Blood samples were collected immediately before and 6 hours after TSH administration. There were no significant differences in post-TSH stimulation T_4 concentrations among the three groups (Boretti et al., 2006). Another study suggested that 50 μg rhTSH was the optimal dose in euthyroid dogs to get a significant increase in serum total thyroxine (TT_4) concentrations (Sauvé and Paradis, 2000). Similarly, IV administration of 25–200 μg rhTSH significantly increased serum TT_4 concentrations 6–8 hours later in euthyroid cats (Stegeman et al., 2003). A previous study with bovine TSH in cats had shown that the peak of serum T_4 was simply extended to later time points with higher dosages (Hoenig and Ferguson, 1983).

Assuming a pharmacological dosage of TSH is used, the diagnosis of hypothyroidism in the dog is usually confirmed when the post-TSH serum T_4 concentration is below the normal range for basal T_4 (usually <1.0 μg/dl or <13 nmol/l in the dog) and rarely increases greater than 0.2 μg/dl (2.6 nmol/l) above the baseline. In pituitary forms of hypothyroidism, the thyroid gland should remain responsive to TSH. The rare cases of long-standing secondary (pituitary) or tertiary (hypothalamic) hypothyroidism with subsequent thyroid atrophy may require two or three consecutive daily doses of TSH to eventually demonstrate thyroid responsiveness (Ferguson, 1984, 1994, 2007).

A study of normal dogs evaluated the predictive value of blood sampling times after 5 units of intravenous TSH: in 80% of the animals, a doubling of the serum T_4

concentration was not achieved by 4 hours but was achieved in all cases by 6 hours post-TSH. Animals that responded favorably to thyroid replacement therapy have, on average, virtually no increase in serum T_4 concentration following TSH. An advantage of the TSH stimulation test is that post-TSH T_4 concentrations tend to be less variable because the thyroid is maximally stimulated.

Thyrotropin: Structural Homology Among Species

The TSH beta subunit is approximately 18 kD in molecular weight, consists of approximately 110–113 amino acids, and contains one *N*-linked complex carbohydrate. TSH, like LH, contains sulfate groups that terminate certain chains; such sulfation is found only to a small extent in FSH and not at all in CG. The genes for the beta subunit of TSH of mouse, rat, human, cattle, sheep, dog, cat, horse, opossum, teleost fish, chicken, quail, and horse have been cloned and sequenced. For most mammalian species, the mRNA is approximately 700 bases in length with minor variations. The TSH beta mRNA encodes the precursor TSH beta subunit with a 20-amino-acid leader sequence and a 117– or 118–amino-acid coding region. There is 80 to 90% homology at the amino-acid level among the sequences of most of the mammalian TSH beta molecules. As an example of avian species, the amino acid sequence of the quail TSH beta subunit shows homologies of about 70% to that of mammalian species, about 60% to that of amphibian, and about 50% to that of teleost fish. There is evidence that the functional domains of the TSH beta subunit and the TSH receptor have diverged cooperatively during evolution. Many regions of identical sequences are apparent in various beta subunits of glycoprotein hormones and the regions around residues 51 through 57 and 75 through 80 in the beta structures are suggested to be involved in interaction with the common alpha subunit (Szkudlinski et al., 2002).

Glycosylation Patterns: Relevance to Bioactivity and Immunoreactivity

The pituitary glycoproteins LH, FSH, and TSH are produced and secreted in multiple molecular forms. In vivo, microheterogeneity of the carbohydrate constituents of the individual hormones causes heterogeneity in affinity for the receptor and in metabolic clearance of the hormone. In vitro, immunoreactivity is affected by this heterogeneity. Much has been learned from studies of human and equine chorionic gonadotropin because of the use of these agents as pharmaceuticals. For example, highly sialylated human FSH variants exhibit lower receptor binding, bioactivity, and immunoactivity compared to less sialylated counterparts. Each isoform appears to have a different affinity for the receptor. For example, FSH glycosylation variants appear to induce or stabilize distinct receptor conformations, resulting in different degrees of activation or inhibition of a given signal transduction pathway. Moreover, the FSH microheterogeneity depends on not only the variations in the sialic acid content but also on the differences in the internal structure of the carbohydrate chains, which determine the full biological expression of FSH glycosylation variants (Creus et al., 2001).

The oligosaccharide chains of pituitary glycoprotein hormones such as human thyroid-stimulating hormone (hTSH) have been shown to be important in biosynthesis, subunit association, secretion, and bioactivity. However, the exact biological significance of these glycosylation isoforms remains controversial. hTSH glycosylation variants more basic in isoelectric point were found to be significantly more active than acidic ones in stimulating cAMP formation; however, there were no differences in stimulation of inositol phosphate release. In support of efforts to develop recombinant pituitary glycoproteins as pharmaceuticals, the bioactivity of glycoproteins produced in vitro appears to be as great as, or in some cases greater than, that of the pituitary derived form (Thotakura et al., 1991). Since glycosylation of plasma hormones is immunologically distinct from pituitary stock (Zerfaoui and Ronin, 1996), an ideal immunoassay standard's recognition should be glycosylation independent. In a study comparing the immunoreactivity and bioactivity of recombinant feline TSH with deglycosylation of recombinant feline TSH, deglycosylation appears not to have reduced the in vitro bioactivity of this product (Rayalam et al., 2006b). No studies have evaluated the rate of clearance of recombinant TSH in domestic species.

Effects of Drugs on TSH Concentrations

This subject has been reviewed (Daminet and Ferguson, 2003; Ferguson, 2007). Drugs with significant effects on the thyroid axis include glucocorticoids and barbiturates. However, suppression of TSH concentrations by glucocorticoids have not been observed, probably due to the lack of sensitivity of the TSH assay.

Two studies (Daminet et al., 1999; Gaskill et al., 1999) have examined the effects of phenobarbital on thyroid function tests. Daminet and coworkers prospectively examined the effect of a 3-week course of phenobarbital on TT_4, free thyroxine by equilibrium dialysis (FT_4D), and TSH, and observed no significant alteration of these values over this time frame. Gaskill and coworkers, in an effort to dissect out the effects of phenobarbital, documented TT_4 and TSH in 78 dogs receiving phenobarbital and compared them with 48 untreated epileptic dogs. Of the dogs on phenobarbital, 40% had low TT_4 and 7% had elevated TSH, while only 8% of untreated dogs had low TT_4 and none had elevated TSH. Of the latter group, only dogs with recent seizure activity had low TT_4 values. The investigators found no effect of phenobarbital on serum binding of T_4. The mean serum TT_4 was significantly lower, and mean serum TSH significantly higher in the phenobarbital-treated group. As with the subacute study (Daminet et al., 1999), there did not appear to be a correlation between phenobarbital dosage or duration of treatment and the serum TT_4 and TSH concentrations.

Dopamine and dopamine agonist bromocryptine were shown to suppress serum TSH in patients with selective pituitary resistance to thyroid hormone (Ohzeki et al., 1993). Other drugs that suppress TSH either at the level of hypothalamus or pituitary include retinoids (vitamin A derivatives) and somatostatin analogues (reviewed by Haugen, 2009).

Somatomammotropins and Regulatory Hormones

Growth hormone and prolactin have similarities in amino acid structure and also share some biological activities. As a result they are called somatomammotropic or somatolactotropic hormones.

Growth Hormone–Releasing Hormone

Growth Hormone–Releasing Hormone (GHRH) is secreted by neurons located in the arcuate nuclei with their axons terminating in external lamina of median eminence. GHRH is synthesized from a precursor of 108 amino acids. Initially, two peptides of 44 and 40 amino acids with GH-releasing activity were isolated. Synthetic peptides that contain only the first 29 amino acid residues of GHRH are shown to be as potent as natural GHRH. GHRH stimulates synthesis and secretion of growth hormone by somatotrophs. GHRH binds to specific cell-surface receptors that are coupled to adenylyl cyclase though G proteins. Cyclic AMP mediates the GHRH effect on GH gene transcription and regulation GH secretion. GHRH also has a mitogenic effect on somatotrophs (Brazeau et al., 1982; Guillemin et al., 1981; Mayo et al., 1983; Michel et al., 1983; Reul et al., 1990). Interestingly, a study has reported that the use of GHRH plasmid-based therapy in companion dogs diagnosed with spontaneously occurring malignancies like hemangiosarcoma and carcinoma survived 84% longer than the placebo treatment group. The GHRH/GH/insulin like growth factor (IGF-I) axis has been implicated in the overall improvement in quality of life of cancer patients (Colao et al., 1999) and in this study, intramuscular treatment with GHRH-plasmid followed by electroporation in dogs with various kinds of tumors improved cachexia-associated anemia and the quality of life. Thus, GHRH-plasmid appears to have a beneficial effect on survivability of dogs with spontaneous tumors and deserves further investigation (Bodles-Brakhop et al., 2008).

Ghrelin

Ghrelin is a 28-amino-acid peptide with *O*-n-octanoylation at the serine in the third position, a modification essential for biological activity. This post-translational modification is unique among known neuropeptides. Ghrelin is produced by the stomach in anticipation of a meal, but has stimulatory effects on GHRH neurons and GH secretion by the pituitary (Kojima et al., 1999; Cone et al., 2003). Ghrelin mRNA and peptide have been detected in human pituitary, indicating that ghrelin is also synthesized within the pituitary, where it may influence the release of GH in an autocrine and paracrine manner (Kamegai et al., 2001). However, the GH-releasing capacity of ghrelin was shown to decline with aging in dogs (Bhatti et al., 2006).

Somatostatin: Growth Hormone Release Inhibiting Hormone

Somatostatin-producing neurons within the CNS are concentrated mainly in the anterior periventricular region of the hypothalamus with nerve terminals in external lamina of the median eminence. However, somatostatin-producing neurons are distributed also in other regions of the CNS and outside the CNS in epithelial cells (D cells) of the gastric mucosa, small intestine, kidney, islets of Langerhans of the pancreas, and parafollicular cells of thyroid. Somatostatin is synthesized as a precursor of 116 amino acids that is processed proteolytically to peptides with 14 or 28 amino acids. Somatostatin exerts its effects by binding to specific receptors on surface of target cells, which interact with G proteins. G proteins mediate a number of intracellular events, namely inhibition of adenyl cyclase activity leading to suppression of cAMP accumulation and inhibition of calcium fluxes leading to enhanced K^+ conductance and hyperpolarization. The fall in intracellular calcium reduces hormone secretion. GHRH also exerts a direct antiproliferative effect, inhibiting DNA synthesis and cell replication by blocking epidermal growth factor-induced centrosomal separation. This action might occur by interfering with movement of microfilaments and by preventing microtubule disassembly by inhibiting calcium influx. Table 26.9 summarizes the wide biological effects of somatostatin (Brazeau et al., 1973; Lamberts, 1986; Montminy et al., 1984; Reichlin, 1983; Schmeitzel and Lothrop, 1990).

Octreotide

Somatostatin has a limited clinical utility because of its short half-life (2–3 minutes) and its multiple effects. Since exogenous somatostatin is rapidly cleared from circulation, a series of longer-acting somatostatin analogs have been developed. The somatostatin analogue octreotide has been used to help manage pituitary disorders (Klonoff and Karam, 1992). Octreotide (Sandostatin®; Novartis) has been employed in the management of acromegaly, gastrinoma, pancreatic beta

Table 26.9 Actions of somatostatin. See text for explanation of abbreviations.

Inhibits hormone secretion by:
Pituitary gland
  TSH, GH, PRL, ACTH
Gastrointestinal tract
  Gastrin
  Secretin
  GIP
  Motilin
  Enteroglucagon
  VIP
Pancreas
  Insulin
  Glucagon
  Somatostatin
Genitourinary tract
  Renin
Inhibits other gastrointestinal actions:
Gastric acid secretion
Gastric emptying
Pancreatic enzyme and bicarbonate secretion
Intestinal absorption
Gastrointestinal blood flow
AVP stimulated water transport
Bile flow

cell tumors, and glucagonoma in the dog. Another long-acting somatostatin analogue, lanreotide (Somatuline® Depot), is currently being researched for use in dogs and has been approved by FDA for treatment of acromegaly in humans.

Pegvisomant

Pegvisomant is a GH receptor antagonist used to treat acromegaly. Pegvisomant is a polyethylene glycol derivative of a synthetic GH and has reduced immunogenicity and prolonged plasma residence time. It does not cross the human blood–brain barrier, there by sparing inhibition of central nervous system GH actions (Veldhuis et al., 2010). Thus, pegvisomant influences GH secretion predominantly by its actions outside the blood–brain barrier, such as the suppression of IGF-I concentrations in peripheral tissues like liver.

Somatotropin: Growth Hormone

Structure and Secretion

Somatotropin (GH) is a polypeptide hormone with a molecular weight of approximately 22 kD. The principal form of human somatotropin is a single chain, 191-amino-acid hormone, as was published in 1969 by Li (Li, 1969). There is considerable species specificity for somatotropin (Kostyo and Reagan, 1976; Wallis, 1975), and human, bovine, and porcine somatotropin used clinically are now commercially produced by recombinant techniques. The sequence of canine growth hormone was first identified in 1994 and that of the cat was identified in 1995 (Ascacio-Martinez and Barrera-Saldana, 1994; Castro-Peralta and Barrera-Saldana, 1995).

Somatotropin is synthesized and released under the influence of growth hormone releasing hormone (GHRH), a 44-amino-acid peptide. The secretion of somatotropin occurs in a pulsatile fashion, which results from the asynchronous release of GHRH and somatostatin (growth hormone inhibition hormone, GHIH), a potent inhibitor of somatotropin release (Müller, 1987). Pulsatile release of GH appears to be the effect of GHRH pulsatile secretion, whereas between-pulse concentrations are largely determined by somatostatin (somatotropin-release inhibiting hormone, SRIH) (Rijnberk, 1996). Many physiological, pharmacological, and pathological factors influence the secretion of somatotropin, including exercise and hypoglycemia, which increase somatotropin secretion, as do α-adrenergic agonists, β-adrenergic antagonists, and dopamine agonists. Glucocorticoids, α-adrenoceptor blockers, and β-adrenergic agonists decrease somatotropin secretion, as do hyperglycemia and obesity. See Table 26.10 for a review of regulatory factors for growth hormone release (Cone et al., 2003).

Table 26.10 Factors influencing growth hormone secretion

Stimulate	Inhibit
Hypoglycemia	Hyperglycemia
Exercise	Free fatty acids
Sleep	Somatostatin
Amino acids	Growth hormone (negative feedback)
Hypoglycemia	Antidiuretic hormone (ADH)
Growth hormone–releasing hormone (GHRH)	
Ghrelin	
Adrenocorticotropic hormone (ACTH)	
α_2-adrenergic agonists (clonidine)	α-adrenergic antagonists
M1 cholinergic agonists	M1 cholinergic antagonists
β-adrenergic antagonists	β_2-adrenergic agonists
Dopamine or agonists	Dopamine antagonists (phenothiazines)
γ-aminobutyric acid (GABA) or agonists	
Histamine 1 agonists	H_1-histamine antagonists
Serotonin agonists	Serotonin antagonists
μ opioids	Neuropeptide Y (NPY)
Testosterone	Progesterone
Estrogen	
Stress glucocorticoids (acute)	Glucocorticoids (chronic)

Function

The receptor for GH is a cell surface receptor and belongs to the JAK/STAT cytokine receptor superfamily. GH has two distinct receptor binding sites and thus dimerization of GH receptors is required for the binding of GH and subsequent activation of the signaling cascade. Growth hormone's effects can be divided into two main categories: rapid or metabolic actions, and slow or hypertrophic actions (Rijnberk, 1996). Acute catabolic effects are mediated by GH by decreasing carbohydrate utilization and impairing glucose uptake into cells, which results in glucose intolerance and secondary hyperinsulinism (Lean et al., 1992). The slower anabolic effects are mediated via IGFs. These hormones are produced in many tissues, particularly liver, in response to somatotropin. Growth hormone, via IGF-1, increases protein synthesis, and decreases protein catabolism by mobilizing fat and increases lean body mass and bone density. This protein-sparing effect is important for linear growth and development. Furthermore, IGF-1 can elicit feedback inhibition to regulate both GHRH and GH secretion.

Therapeutic use

Small animal applications: In young dogs, growth hormone deficiency can occur as a primary endocrine abnormality resulting in pituitary dwarfism. It may be treated with bovine, porcine, or human somatotropin. Porcine somatotropin (pGH) is structurally identical to canine somatotropin and may be preferred for treatment in the dog (Ascacio-Martinez and Barrera-Saldana, 1994). The pharmacological and toxicological effects of exogenous porcine somatotropin administration in normal adult dogs was evaluated. The results indicated that pGH caused: a dose-dependent increase in body weight and the weights of liver, kidney, thyroid, and pituitary gland; increased skin thickness; and increased serum IGF-1 levels. However, minimal or no biologically significant effect of pGH on serum T_3, T_4, and cortisol levels in dogs was noticed (Prahalada et al., 1998).

Preparations and dosage protocols: It has been recommended to administer somatotropin at 0.1 IU/kg to dogs subcutaneously three times weekly for 4–6 weeks (Eigenmann, 1982). If ACTH and TSH secretion are also abnormal, the animals need to be treated with replacement doses of glucocorticoids and thyroid hormone. Growth hormone–responsive dermatosis has been treated successfully with 0.15 IU/kg two times weekly for 6 weeks (Schmeitzel and Lothrop, 1990).

Large animal applications: Bovine somatotropin (bST) has been used in cattle for several reasons. Somatotropin improves feed efficiency and leads to an effective increase in protein and reduction of fat, thus providing a desirable carcass in terms of degree of fatness and meat quality (Groenwegen et al., 1990; Schwarz et al., 1993). This has also been seen when bST was administered in finishing lambs (McLaughlin et al., 1993). In the pig, porcine somatotropin also leads to increased growth rates and improved meat quality (Campbell et al., 1988; Etherton et al., 1987). A study has indicated that use of bST was effective in reducing carcass fat and increasing edible lean of Holstein steers, but administering bST to young lightweight steers decreased carcass quality (Schlegel et al., 2006).

Treatment with bST was shown to improve fertilization rate, accelerate embryo development, and improve embryo survival. Presence of a conceptus altered endometrial expression of genes and proteins in response to bST to improve pregnancy rates (Moreira et al., 2002).

In addition to improvements in meat quality and fertility, bST has been used to increase milk production in the cow, and in the USA, this application has been approved since 1994. Somatotropin also has an effect on milk composition, resulting in less short- and medium-chain fatty acids and more long-chain fatty acids (Bauman, 1992, 1999; Lean et al., 1992).

Bovine milk naturally contains less than 1 ng/ml of GH whereas humans secrete 500–875 µg GH per day. GH does not significantly increase in milk when cows are treated with recombinant bST. Bovine growth hormone itself is degraded by the gastric acid when ingested orally and it is reported that the amino acid sequence of bST differs from that of hST by approximately 35% and as a result human growth hormone receptors do not respond to bST (bovine GH) (Lesniak et al., 1977).

Administration of bST increases IGF-1 concentrations in bovine milk, and some researchers have postulated that dairy products may increase the risk of breast cancer due to their content of fat, IGF-1, estrogens, or growth hormone. However, a metaanalysis review concluded that the available evidence does not support this association. Although IGF-1 concentrations are not affected by pasteurization, the average milk content of IGF-1 has been estimated at 4 ng/ml. Based upon a 1.5 l/day milk intake, this would contribute 6 µg of IGF-1 to the gastrointestinal tract. About 380 µg are contributed by gastrointestinal secretions. These amounts compare to the 10,000 µg produced daily in the liver and extrahepatic tissues. Thus, milk-derived IGF-1 is estimated to contribute less than 0.06% of the total IGF-1, and that would likely be an overestimate as it assumes that all IGF-1 survives proteolysis in the gastrointestinal tract (Parodi, 2005).

It is important to note, however, that the European Union (EU) currently has a moratorium banning the use of bST in order to increase milk yield. An immunoassay for IGF-1 concentrations in milk has been developed and proposed as a regulatory test in milk samples.

Preparations and dosage protocols: Several formulations of bovine somatotropin (bST) are on the market. These include a daily dose, and 7, 14, and 28-day prolonged release preparations. The 14 and 28-day preparations are methionyl bST preparations. Exogenous bST must be present every day in order to continue an augmented milk response. The reason is that the bST peptide is rapidly cleared from the body. When given to cattle daily, maximum milk response is achieved with bST doses of 30–40 mg/day, and no further increase is observed with higher doses. Most production trials have employed doses between 10 and 50 mg/day. Posilac® (Monsanto) is 500 mg of met^{-1} . . . leu^{126} recombinant bovine somatotropin (Sometribove, USAN), a 14-day prolonged release preparation of bST (Sometribove, USAN), which is administered every 14 days. Milk yield generally increases the first few days of bST treatment, reaching the maximum on about the sixth day. In swine, prolonged release (4–6 weeks) injectables or ear tags are also available (Bauman, 1992, 1999; Lean et al., 1992).

Adverse effects

In dogs, diabetes mellitus is the major potential side effect of growth hormone administration; therefore, fasting blood glucose concentrations should be determined before and at weekly intervals while on growth hormone therapy. Hypersensitivity reactions might also occur after treatment with growth hormone (Schmeitzel and Lothrop, 1990).

In cattle, treatment with growth hormone has been reported to cause an initial decrease in food intake; however, after a few weeks an increase is seen. It has also been suggested that growth hormone treatment increases the incidence of mastitis, which may be a function of the increase in milk production (Bauman, 1992, 1999; Lean et al., 1992). However, in a multinational study involving over 900 cows no effect on incidence of clinical mastitis was seen (White et al., 1994). There are no indications that growth hormone administration leads to an increase in metabolic diseases in this species (Bauman, 1992, 1999; Lean et al., 1992).

Mecasermin

Mecasermin (Increlex®; Cambrex Bio Sciences Baltimore, Inc.) is a recombinant human IGF-1. It is a single-chain, nonglycosylated 70-amino-acid protein connected via three disulphide bonds. The amino acid sequence of mecasermin is identical to the native IGF-1. Mecasermin is approved by FDA for treatment of severe IGF-1 deficiency that is not responsive to GH in humans. Use of mecasermin in veterinary medicine is still under research.

Prolactin

Structure and biosynthesis

Prolactin (PRL) is a 198-amino-acid polypeptide hormone with a molecular weight of 22,000, which is synthesized and secreted by the lactotrophs of the anterior pituitary. It is classified as a somatomammotropic hormone and about 10–15% of the molecule represents glycosylation. Although glycosylated PRL is less potent, the glycosylation appears to stabilize the molecule to degradation in the body. In the species for which its structure has been identified, PRL has three intrachain disulfide bridges. The amino acid sequences of canine and feline prolactin have been identified (Gomez-Ochoa et al., 2004; Warren et al., 1996).

There are no pharmaceutical preparations of this hormone and few, if any, therapeutic applications. Prolactin regulation is of relevance to the reproductively cycling animal in a variety of species. PRL evolved from a hormone common to GH and human placental lactogen (hPL), but it now shares only a minority of residues (13 and 16%, respectively) with these hormones. The precursor molecule for PRL is a 227 amino acid with a molecular weight of 40,000 to 50,000 and contributes to some of the plasma PRL immunoreactivity (Klonoff and Karam, 1992; Tyrell et al., 1994).

Function

PRL stimulates lactation in the postpartum period. It appears to have functions related to reproduction, particularly related to the care, feeding, and protection of offspring, even in fish and birds. Prolactin seems to have effects on salt and water metabolism, and is important in the ability of the salmon, for example, in changing from a saltwater to a freshwater environment. In mammals, the increasing concentrations of prolactin during pregnancy, combined with the hormonal effects of estrogens and progestins, induce the development of mammary tissue. In rodents, prolactin prolongs the life of the corpus luteum, but does not perform this function in humans or domestic mammals. The secretion of prolactin with suckling in certain species, most notably humans, is also likely to inhibit ovarian function and prevent ovulation and fertility (Klonoff and Karam, 1992; Tyrell et al., 1994).

Regulation of secretion

Secretion of prolactin by the pituitary is normally under inhibitory control by the hypothalamus, specifically by the neurotransmitter dopamine. Therefore, dopamine agonists inhibit prolactin secretion very effectively in hyperprolatinemia. Dopamine agonists like bromocriptine (Cycloset®) shrink pituitary prolactin-secreting tumors, lower circulating prolactin levels and restored ovulation in 70% of women with microadenomas (Webster et al., 1994), and suppress PRL and hence progesterone in pregnant bitches (Onclin et al., 1995). Factors influencing secretion of growth hormone often have similar effects on PRL: sleep, stress, hypoglycemia, and exercise all increase PRL and GH. Other PRL-releasing hormones include TRH, which may explain galactorrhea in some hypothyroid bitches. Also the dopamine antagonists phenothiazines and metoclopramide, as well as butyrophenones, increase prolactin secretion. The half-life of prolactin in plasma is only 15–20 minutes. A prolactin inhibiting hormone (PRIH) of peptide nature has been investigated in rats. In humans, heavy athletic training, likely through opioid release, may inhibit PRL production and result in reproductive alterations, specifically amenorrhea in women (Kuret and Murad, 1990).

Therapeutic uses

There are no applications of clinical relevance. Milk production in cattle does not seem to be limited by the usual concentrations of circulating prolactin. However, research has focused upon the ability of GH to be galactopoietic.

Posterior Pituitary Hormones

There are two known posterior pituitary hormones: vasopressin (antidiuretic hormone, ADH) and oxytocin. Both hormones differ from vasotocin found in nonmammalian vertebrates by only one amino acid. Posterior pituitary hormones are synthesized in the hypothalamus and transported to the posterior pituitary where they are stored and released into the circulation.

Antidiuretic Hormone

Two nine-amino-acid peptides are secreted by the neurohypophyseal system: ADH (or arginine vasopressin, AVP) and oxytocin. They are synthesized by the magnocellular neurons of the supraoptic nuclei and the lateral and superior parts of the paraventricular nuclei. ADH regulates the water permeability of the distal tubules and collecting duct of the nephron. It also is a vasoconstrictor and influences cardiovascular function.

Structure

Antidiuretic hormone has a molecular weight of 1084 and is characterized by a six-amino-acid ring and a three-amino-acid side chain with a disulfide linkage. The prohormone for ADH includes the ADH sequence and neurophysin II, which binds to ADH. Following synthesis of the peptide, secretory granules containing the prohormone move down the axon to the nerve terminal in the posterior lobe of the pituitary. Upon exocytosis, equimolar amounts of the neurophysin and ADH are released. The neurons also project to the choroid plexus where they also release ADH into the cerebrospinal fluid.

Stimuli for Release

The primary physiological stimulus for ADH release is an increase in plasma osmolality. However, hypovolemia, pain, exercise, and some drugs may stimulate ADH release.

Mechanism of Action

Three receptor subtypes that mediate the actions of AVP have been identified (V_{1A}, $V_{1B,}$ and V_2). V_{1A} receptors are located in vascular smooth muscle cells and the heart, and mediate vasopressin-induced vasoconstriction and increased afterload. The V_{1B} receptor is located in the anterior pituitary and mediates ACTH release. V_2 receptors are found on the renal tubule cells and are involved in the mediation of antidiuresis through increased water permeability and water reabsorption in the collecting ducts. ADH increases cyclic AMP in the tubule, which increases water permeability by stimulating the insertion of aquaporin 2 proteins at the luminal surface, resulting in increased water permeability and reabsorption, urine osmolality, and decreased urine volume. V_2 receptors outside of the kidney also mediate the release of the coagulation factor VIII and von Willebrand's factor. Aside from its value in treating conditions like central diabetes insipidus where vasopressin is deficient, irreversible shock has also been postulated to be exacerbated by a vasopressin deficiency, leading to its use in shock therapy.

Desmopressin acetate (DDAVP, 1-desamino-8-D-arginine vasopressin) is a long-acting synthetic analogue of predominately V_2 and is a potent antidiuretic. Several nonpeptide AVP antagonists, like vaptans, conivaptan (Vaprisol®), and tolvaptan (Samsca^{TM}), have been developed, and are being evaluated, and are approved by the FDA, for administration in hyponatremia and fluid overload in humans (Ali et al., 2007).

Table 26.11 summarizes the actions of vasopressin and the respective ADH receptors (V_{1A}, V_{1B}, and V_2) mediating the actions.

Absorption, Metabolism, and Excretion

Vasopressin must be administered parenterally and has a very short half-life of about 20 minutes.

Preparations

Natural and synthetic ADH is available commercially for the diagnosis and treatment of diabetes insipidus. Dogs, cats, horses, and humans produce arginine-ADH and pigs produce lysine ADH. Desmopressin or deamino-D-arginine vasopressin (DDAVP) is available for parenteral (subcutaneous) injection; the acetate form is available for nasal administration and as 0.1 and 0.2-mg tablets.

Table 26.11 Actions of vasopressin

Target organ	Receptor type	Action
Renal glomerulus	V_1	Mesangial cell contraction
Vasa recta	V_1	Decrease medullary blood flow
Juxtaglomerular cells	V_1	Suppress renin release
Arterioles	V_1	Constriction
Liver	V_1	Increase glycogenolysis
Anterior pituitary	V_1	Increase ACTH release
Baroreceptors	?	Desensitization or sensitization of baroreflex
Cortical and medullary collecting tubules	V_2	Increase H_2O permeability
Papillary collecting ducts	V_2	Increase H_2O permeability
Thick ascending loop of Henle	V_2	Increase Na^+, K^+, Cl^- reabsorption

Diagnosis of Diabetes Insipidus

Diabetes insipidus (DI) is caused by the deficiency of antidiuretic hormone (central DI) or by absence of a renal response to this anterior pituitary hormone (nephrogenic DI). The main presenting signs, in the absence of other conditions, are polyuria and polydipsia.

Central DI is due to the absolute deficiency of antidiuretic hormone (vasopressin; ADH). In partial central DI, some endogenous ADH secretion remains. These conditions are the result of the destruction of the supraoptic and paraventricular nuclei of the hypothalamus, which have axons terminating in the posterior pituitary. The damage may be due to head trauma from surgical transection of the pituitary stalk (usually only transient DI) or primary or metastatic tumors, or (most commonly in veterinary medicine) the cause is not known (idiopathic DI).

Nephrogenic diabetes insipidus results when the renal tubule is insensitive to ADH. In this condition, ADH does not increase intratubular cAMP concentrations, a necessary prerequisite to the increased water permeability normally induced by ADH. This abnormality of ADH responsiveness may also be partial or total. Primary causes of nephrogenic diabetes are rare. However, secondary nephrogenic DI may result from pyometra, liver disease, hyperadrenocorticism, hyperthyroidism, hypercalcemic disorders, renal failure, and pyelonephritis.

Diabetes insipidus is diagnosed if the urine specific gravity is dilute (less than 1.008) in the face of dehydration and/or an elevated plasma osmolality. However, it is not infrequent for the animal to present in a hydrated state and to have a normal or only slightly elevated plasma osmolality. A modified water deprivation test is recommended to confirm that endogenous ADH and urine osmolality will not rise in the face of moderate dehydration. Following carefully monitored gradual water withdrawal over 3 days, water is completely withdrawn on the 4th day and the urine osmolality and plasma osmolality are monitored. If greater than 5% dehydration is achieved and no urine concentration is observed, exogenous ADH is administered to test the ability to respond to exogenous hormone.

Vasopressin can be administered in the following manner in this test:

The administration of 1 milliunit/ml of aqueous ADH (Vasostrict®, Par Sterile Products Vasopressin USP) in Lactated Ringer's or 5% dextrose. This solution is administered IV over 1 hour at the rate of 10 ml per kg body weight. Urine samples should be obtained at 15-minute intervals for 90 minutes following ADH administration.

In an animal with complete central DI, the urine osmolality will not have risen above isoosmolality (300 mOsm per kg) with dehydration, and subsequent ADH administration will increase urine osmolality at least 50%.

In an animal with partial central DI, the urine osmolality will increase above isoosmolality, but it will increase an additional 10–50% following exogenous ADH.

Animals with nephrogenic DI do not concentrate their urine upon dehydration above isoosmolality, and also do not respond to exogenous ADH.

Therapeutic Uses

Aqueous ADH or ADH analogues are currently the only formulations available for the treatment of total and partial central DI. Synthetic ADH analogues DDAVP (DDAVP®, Stimate®, Minirin®, Ferring Pharmaceuticals) and LVP (lysine-8-vasopressin, Lypressin®, Diapid Nasal Spray®, Novartis) are the most commonly used. Both of these preparations can be administered intranasally or into the conjunctival sac. The latter route appears to be better tolerated by the animals. Ocular or conjunctival irritation is a rare problem.

DDAVP is a drug with greater potency and slower metabolism than the natural ADH molecule. Administration of 5–20 μg of DDAVP (2–4 drops) in single or divided doses controls polyuria in most animals. The peak drug action is seen at 2–6 hours and its duration may last from 10 to 27 hours. The clear advantage of this medication is that it does not require parenteral administration. However, the conjunctival route results in variable amounts of drug reaching the blood stream and variable duration of effect even in the same patient. DDAVP is also quite expensive and therefore it might be prudent to use the drug only when polyuria is observed or to avoid excessive nocturnal urine production.

LVP is another product that is available for managing DI via nasal or conjunctival administration. However, its duration of action is shorter and expense greater than the other products. As a result, it has not found much application in veterinary medicine (Chastain and Ganjam, 1986; Ferguson et al., 1992).

DDAVP has also been used for bleeding disorders (von Willebrand's disease and hemophilia A). In pharmacological doses, it increases plasma levels of factor VIII:C and von Willebrand factor, via preferentially increasing levels of larger von Willebrand factor multimers and by increasing platelet adhesion. Controlled studies on the use of DDAVP in dogs are lacking, but the clinical impression is that DDAVP is beneficial in some, but not all, von Willebrand's dogs. The initial parenteral dose of DDAVP (with either preparation) is 0.5–2 μg SQ once or twice daily. In animals, administration as eye drops is often more convenient. For chronic therapy of central diabetes insipidus, the DDAVP tablets are dosed initially at 0.1 mg given three times a day. The dose is gradually increased to effect if there still is unacceptable polyuria and polydipsia persisting a week after starting therapy. Most dogs require 0.1–0.2 mg of DDAVP two to three times a day for chronic therapy.

Toxicity

Immediately following a dose, in order to avoid water intoxication, dogs should not be given unlimited quantities of water. The transiently high levels of ADH will prevent the excretion of a free water load by the kidney and result in overhydration and possible neurological sequela such as cerebral edema. Cerebral edema may be manifested by depression, vomiting, salivation, ataxia, muscle tremors, and convulsions. Animals with central or nephrogenic DI disease may also be successfully managed by providing free access to water at all times and by housing the animals outdoors. Another inexpensive maneuver that reduces the urine output is the restriction of dietary sodium using homemade diets or the commercial diets designed for use in congestive heart failure (e.g., Hill's H/D). Such products generally contain less than 0.1% sodium on a dry weight basis (Ferguson et al., 1992).

Other Drugs for Treatment of Central Diabetes Insipidus

Oral agents have also been used primarily as adjuncts to ADH therapy of central DI. Chlorpropamide (Diabinese®, Pfizer), a sulfonylurea hypoglycemic agent used to treat noninsulin-dependent diabetes in humans, has produced inconsistent antidiuretic effects in the dog and cat. Chlorpropamide's effect is to enhance the effect of ADH on the renal tubules and collecting duct by increasing intracellular cyclic AMP. It may also stimulate pituitary ADH release. As a result, it is only effective in the presence of sufficient endogenous (partial central DI) or exogenously administered ADH. Careful dosage studies for chlorpropamide have not been performed in the dog. Reported doses include 250 mg every 12 hours and 10–40 mg/kg/day. Reduction in urinary volumes ranging from 18 to 50% has been reported. Maximal antidiuretic effects take 1–2 weeks to develop. Side effects of hypoglycemia can be minimized by frequent feedings and periodic monitoring of blood glucose concentrations.

Carbamazepine (Tegretol®, Novartis), an antiepileptic, is also effective in some cases of central DI. In contrast to the other drugs, these agents may increase the secretion of ADH and therefore would be rational therapy only in partial central DI. Likewise, indapamide (Mylan Pharms Inc.), an antihypertensive diuretic drug that increases urinary osmolality and decrease serum osmolality, appears to be effective in the mild form of central DI. However, there have been no reports in the veterinary literature of the use of these drugs for the successful treatment of DI.

Thiazide diuretics when used together with salt restriction may serve to potentiate the effect of exogenous or endogenous ADH (see Section Treatment of Nephrogenic Diabetes Insipidus) (Ferguson et al., 1992; Klonoff and Karam, 1992; Tyrell et al., 1994).

Treatment of Nephrogenic Diabetes Insipidus

Treatment for nephrogenic DI should, if possible, start with correction of the underlying cause of the nephrogenic DI (hypercalcemia, renal infection, hyperadrenocorticism without a compressive pituitary tumor). Except for institution of a low-sodium diet, the thiazide diuretics are the only agents that have been shown to be effective in the treatment of nephrogenic DI.

Thiazide diuretics have a paradoxical antidiuretic effect in central and nephrogenic DI. These agents may reduce the reabsorption of sodium in the ascending loop of Henle, resulting in enhanced urinary sodium loss, mild reduction in plasma osmolality, and, therefore, diminished thirst. The reduction in water intake causes contraction of the extracellular volume, and proximal tubular sodium reabsorption is increased and the glomerular filtration rate decreased. The urine volume is thereby reduced without overt concentration of the urine osmolality. Hydrochlorothiazide (Microzide®, Watson Labs) at a dosage of 2.5–5 mg/kg has succeeded in reducing water intake by 50–85% in cases of ADH-resistant polyuria. Due to the kaliuretic effect of the thiazides, serum potassium should be monitored and oral potassium gluconate administered if the animal becomes anorexic (Ferguson et al., 1992). However, in human patients, combined use of thiazide diuretics and selective serotonin reuptake inhibitors synergistically impaired renal free water clearance resulting in severe hyponatremia (Rosner, 2004).

Oxytocin

Oxytocin, like vasopressin, is a nine-amino-acid peptide with an intrapeptide disulfide cross-link. It induces contraction of smooth muscle, most importantly of the myoepithelial cells of the mammary gland, which results in milk ejection. Furthermore, it also results in uterine smooth muscle contraction, an effect that increases during pregnancy. Oxytocin increases the release of prostaglandins and leukotrienes that augments the uterine smooth muscle contraction. Its clinical use in the management of milk letdown and uterine contraction (induction of parturition and treatment of pyometra) is described in detail in Chapter 27. Oxytocin is also involved in endocrine and neuroendocrine regulation through receptor-mediated actions exerted on the heart, vasculature, and kidneys (Gutkowska et al., 1997; Jankowski et al., 2000; Conrad et al., 1993).

Mechanism of Action

Oxytocin acts through G-protein coupled receptors and affects the transmembrane ionic currents in uterine smooth muscle cells resulting in sustained uterine contraction. Oxytocin-induced myometrial contractions can be inhibited by tocolytic agents such as β-adrenergic agonists, magnesium sulfate, and inhalation anesthetics (Klonoff and Karam, 1992; Tyrell et al., 1994). Oxytocin receptor antagonist atosiban (Tractocile®) is indicated for tocolysis in preterm labor outside the United States; however, this drug is not tested for veterinary use.

Hormones Affecting Reproduction

Wolfgang Bäumer, C. Scott Bailey, and John Gadsby

Introduction

The brain (hypothalamus) regulates overall reproduction in animals via the synthesis and release of several peptide hormones. It is affected by the physiological status of the animal, and (depending on species) by environmental cues. The best-described and most potent environmental factor is day length, which affects gonadotropin secretion by inhibiting melatonin secretion. Hypothalamic hormones are released from hypothalamic neurons in the region of the median eminence, and they reach the anterior pituitary through the hypothalamic–adenohypophyseal portal system. The two main hypothalamic hormones relevant to reproduction are gonadotropin releasing hormone (GnRH) and the prolactin-inhibitory hormone known as dopamine. The primary function of these hormones is to stimulate or inhibit the release of specific anterior pituitary hormones.

The pituitary gland is essential for the regulation of reproduction, as well as growth, stress, and intermediary metabolism. The pituitary gland consists of three separate lobes in vertebrates: the *anterior (adenohypophysis), posterior (neurohypophysis),* and *intermediate lobes.* The anterior pituitary lobe releases two distinct types of reproductive "trophic" hormones: the gonadotropins (follicle stimulating hormone, FSH, and luteinizing hormone, LH) and prolactin. Based on evolutionary and structural considerations, FSH and LH are grouped together and are glycoprotein hormones, while prolactin is related to growth hormone and is known as a somatomammotropin. A large number of reproductive states as well as a diverse group of drugs also affect their secretion and function (Wright and Malmo, 1992; Driancourt, 2001; Wiltbank et al., 2011).

Steroid hormones play vital roles in reproduction. The ovary (females) and testis (males) are the primary sources of reproductive steroid hormones in animals. The gonadotropins, FSH and LH, which are secreted in response to hypothalamic GnRH, stimulate the secretion of gonadal steroids (primarily estrogens and progesterone in the female, and testosterone and estrogen in the male). A list of hormones and drugs affecting reproduction is summarized in Table 27.1.

Estrous Cycle

In females, GnRH from the hypothalamus and the gonadotropins, FSH and LH, from the pituitary, regulate the estrous cycle (Figure 27.1). GnRH secreted from the hypothalamus is transported by the hypophyseal portal blood vessels to the pituitary gland, where it increases secretion of the gonadotropins, FSH and LH. Gonadotropins stimulate the secretion of gonadal steroids (estrogens and progesterone). Estrogens and progesterone have prominent stimulatory effects upon the female reproductive tract and the mammary gland, while increased circulating levels of these steroids decrease gonadotropin secretion (via negative feedback). Each estrous cycle consists of the following phases:

1) Follicular phase (= proestrus and estrus): during the follicular phase ovarian follicles (one or more depending on the species) develop and mature, secreting increasing amounts of estrogen. These increased amounts of estrogen trigger a surge in release of LH from the pituitary gland, causing ovulation of follicles and the release of ova into the oviduct (see ** in Figure 27.1; except in the queen and in camelids, which are induced ovulators).
2) Luteal phase (= metestrus and diestrus): following ovulation the remnants of each follicle develop into a corpus luteum, whose primary function is secretion of progesterone, which is required to act on the uterus to create an environment compatible with attachment/ implantation of the embryo. If the ova are not fertilized, or if embryos fail to develop or attach/ implant, the corpus luteum regresses (degenerates) in

Table 27.1 Reproductive hormones and related agents

Hormone	Indications
Gonadotropin releasing hormone (GnRH) and gonadotropins	
GnRH	Ovulation induction, infertility therapy
Gonadorelin (synthetic GnRH)	Ovulation induction, infertility therapy
Follicle stimulating hormone (FSH)	Follicle development for embryo transfer
Human chorionic gonadotropin (hCG)	Ovulation induction, infertility therapy
Equine chorionic gonadotropin (eCG)	Ovulation induction, infertility therapy
Oxytocics (ecbolics = uterotonics)	
Oxytocin	Labor induction, milk letdown
Progestins	
Altrenogest	Synchronization of estrus in mare and pig
Melengestrol acetate (MGA)	Synchronization of estrus in cattle
Progesterone (injectable or intravaginal delivery – CIDR)	Synchronization of estrus in cattle, sheep, goats, and mare
Androgens	
Nandrolone	Catabolic disease states in horses and dogs
Stanazolol	Catabolic disease states in horses and dogs
Antiandrogens	
Finasteride	Benign prostatic hypertrophy in dogs
Prostaglandins	
Lutalyse®	Regulation of the estrous cycle in ruminants (e.g., cows) Induction of abortion (various species)
Estrumate® (cloprostenol)	Induction of parturition in sows Induction of abortion (various species)

most species, leading to the cessation of progesterone secretion. However, during pregnancy, the life-span of the corpus luteum is lengthened (except in the bitch), resulting in continued progesterone secretion, which is necessary for pregnancy maintenance.

In nonpregnant polyestrous animals, during the late stages of the luteal phase of the estrous cycle, the uterus (endometrium) releases a hormone called prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$). This hormone causes corpus luteum regression and a decline in progesterone secretion. The withdrawal of progesterone removes negative feedback control on the hypothalamus/ pituitary, allowing increased gonadotropin secretion and the initiation of another estrous cycle (follicular phase followed by luteal phase). It is not secreted in detectable amounts in nonpregnant domestic carnivores (dogs and cats), resulting in a much longer return to estrus in these species. During the breeding season, estrus (female reproductive behavior induced by follicular estrogen) follows corpus luteum regression within a few days.

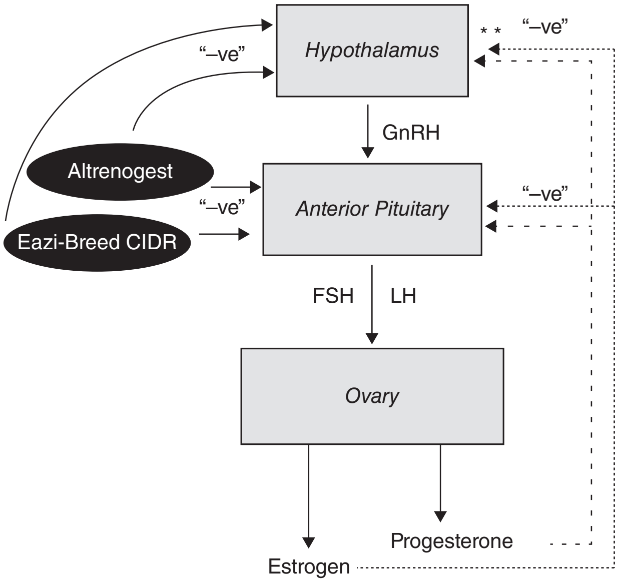

Figure 27.1 Regulation of estrous cycle and gonadal hormone secretion. Gonadotropin-releasing hormone (GnRH) stimulates gonadotropin (follicle stimulating hormone, FSH; luteinizing hormone, LH) release, which subsequently increases ovarian steroid hormone production during the estrous cycle. Like natural estrogen and progesterone, synthetic agents such as altrenogest and melengestrol acetate (MGA) control the estrous cycle by *negative feedback* mechanisms. Note: ** indicates that estrogen at high levels during the follicular phase of the natural estrous cycle, induce a positive feedback effect on the hypothalamus to generate GnRH and LH-surges, resulting in ovulation. CIDR, controlled internal drug release.

The onset and maintenance of cyclicity are coordinated by a complex set of negative and positive feedback mechanisms. Consequently, therapeutic administration of natural or synthetic hormones have been used extensively in the control and synchronization of estrous cycles for breeding purposes (discussed in the sections on each drug in this chapter). Progesterone-like hormones (progestins; e.g., MGA or altrenogest) are the frequently used hormones in theriogenology (Wright and Malmo, 1992).

Gonadotropin-Releasing Hormone, Gonadorelin, and Gonadotropins

The neurohormones such as GnRH (and analogs), gonadotropins (FSH and LH), prolactin and oxytocin, that are important in veterinary medicine are discussed here.

Gonadotropin-Releasing Hormone

Structure and Function

Gonadotropin-releasing hormone (GnRH) is the decapeptide hypothalamic-releasing hormone responsible for stimulating the release of gonadotropins, FSH and LH, by the anterior pituitary gonadotropes. GnRH has a very short half-life (2–4 minutes), is released intermittently (in pulses) and its release is controlled by a neural pulse generator in the hypothalamus. Such intermittent release is crucial for the proper synthesis and release of the gonadotropins, which also are released in a pulsatile fashion (Peters, 2005). Both gonadotropins and gonadal steroids regulate GnRH production in a negative feedback manner (Peters, 2005).

Mechanism

GnRH stimulates the synthesis and release of gonadotropins by binding to the GnRH receptor, a G protein-coupled receptor linked to the IP_3-Ca^{2+} signal transduction pathway. Pulsatile or episodic administration of GnRH stimulates the secretion of gonadotropins and forms the basis of infertility therapy and ovulation induction by increasing gonadal stimulation (see Section Clinical Uses, i). Alternatively, continuous administration of GnRH leads to desensitization and down-regulation of GnRH receptors on pituitary gonadotropes. This leads to the suppression of gonadotropin secretion and forms the basis for the clinical use of long-acting GnRH analogs (e.g., *gonadorelin*) to cause medical castration (see Section Clinical Use, ii) (Stout and Colenbrander, 2004).

Clinical Uses

The two principal uses of GnRH are: (i) induction of ovulation or follicular luteinization, and (ii) suppression of gonadotropin secretion (medical castration). A number of clinical GnRH analogs have been synthesized. These include synthetic GnRH (gonadorelin and buserelin) and other potent, long-acting GnRH analogs (e.g., deslorelin).

Gonadorelin

Gonadorelin (Cystorelin® or Factrel®) is a synthetic preparation of GnRH used to treat animals that fail to ovulate or develop follicular cysts. Deslorelin is available for horses and dogs as a SQ implant (Ovuplant®) or injectable formulation (Sucromate®). Both stimulate the synthesis and secretion of FSH and LH by interacting with GnRH receptors on the pituitary gonadotropes. However, the continuous exposure to gonadorelin or deslorelin leads to desensitization and down-regulation of GnRH receptors on pituitary gonadotropes, which may be the basis for its clinical use to limit estrus in some animals. Thus, the response to these GnRH analogs depends on the dose and time course (first stimulatory, then long-term inhibitory) (Thatcher et al., 2001; Johnson et al., 2002).

Uses

1) Ovulation induction. Gonadorelin has been used empirically to induce ovulation at the time of breeding in both cattle and horses, and is a component of the "Ovsynch" protocol. Due to physiological differences (a prolonged LH surge, lasting 24–36 hours) in horses, a single dose of gonadorelin is insufficient for reliable ovulation induction, and a long-acting formulation of deslorelin is more commonly used (Ferris et al., 2012). Gonadorelin has also been advocated for treatment of stallions with lowered libido. It is used in pulse-dosing to induce estrus in dogs and in cats with prolonged anestrus.
2) Cystic ovaries therapy. Gonadorelin is the drug of choice for treatment of *ovarian follicular cysts* ("cystic ovaries") in cattle (and camelids). Ovarian follicular cysts in cows are defined as follicle-like structures that persist rather than ovulate. These are more than 25 mm in diameter and have been present for 10 days or more in the absence of a corpus luteum. Their occurrence is frequent in the postpartum dairy cow, but rare in beef cows (Farin and Estill, 1993). The first choice for treatment is 100 μg GnRH, which generally results in luteinization of the cystic structure, with estrus occurring in 18–23 days. The administration of $PGF_{2\alpha}$ 9 days after GnRH will often shorten the interval to estrus (see Section Prostaglandin Analogs).
3) Estrus synchronization in conjunction with $PGF_{2\alpha}$: "Ovsynch" or "timed artificial insemination (AI)" protocol in cows (Lucy et al., 2004; Lamb et al., 2010; Wiltbank et al., 2011): Day 0, 100 μg GnRH; Day 7, 25 mg $PGF_{2\alpha;}$ Day 9, 100 μg GnRH; breed cattle by AI 20–24 hours after second GnRH. This allows synchronization of estrous cycles for AI without estrus detection.
4) Timed embryo transfer protocol, for recipient cows (Al-Katanani et al., 2002): using the "Ovsynch" treatment protocol as above, but instead of AI, transfer embryos into recipients on day 16–17. This enables preparation of recipients and embryo transfer without the need for estrus detection.
5) Gonadorelin is used in ferrets and induced ovulators (cats and camelids) to terminate estrus.
6) Gonadorelin can be used experimentally for diagnostic purposes to differentiate between pituitary and hypothalamic defects in dogs with hypogonadotropic hypogonadism.

7) Gonadorelin is also used to identify intact, from spayed or neutered, animals by estimating gonadorelin-stimulated release of FSH and LH.
8) Long-acting GnRH agonists (Ovuplant®) have been used successfully to inhibit cyclicity in domestic dogs and cats (Gobello et al., 2007).

Dosage

Veterinary products are listed in Table 27.2.

Gonadotropins

Secretion and Function

The pituitary hormones, FSH and LH, as well as the related hormones, *human chorionic gonadotropin* (hCG) and *equine chorionic gonadotropin* (eCG or pregnant mares serum gonadotopropin, PMSG), are referred to as the "gonadotropic" hormones. Each hormone is a glycosylated heterodimer containing a common α-subunit and a distinct β-subunit that confers specificity of action. A single hypothalamic releasing factor, GnRH, controls the synthesis and release of pituitary gonadotropins, LH and FSH, in males and females. LH and FSH are synthesized and secreted by gonadotropes, which make up ~20% of anterior pituitary cells. Gonadal steroid hormones (androgens, estrogens, and progesterone) cause feedback inhibition at the level of the pituitary and the hypothalamus to decrease pituitary gonadotropin secretion. The preovulatory surge of estrogen also can exert a stimulatory effect on the hypothalamus and thus promote pituitary gonadotropin surge release (Day, 2004). hCG is produced only in primates and is synthesized by syncytiotrophoblast cells of the placenta. eCG is produced only in equids and is secreted from the endometrial cups of pregnant mares in early pregnancy.

- *In males,* LH acts on testicular Leydig cells to stimulate the synthesis of androgens, primarily testosterone. FSH acts on the Sertoli cells to stimulate the production of proteins and nutrients required for the regulation of sperm production and maturation.
- *In females,* FSH and LH stimulate the growth and development of ovarian follicles, and thereby stimulate the follicle to produce estrogen, while LH induces ovulation and stimulates the developing corpus luteum (after ovulation) to secrete progesterone.

Mechanism

The actions of LH are mediated by the LH receptor, and those of FSH are mediated by the FSH receptor. Human chorionic gonadotropin and eCG variably stimulate one or both of the receptors, with the primary response being mediated via the LH receptor in most species. Interestingly, the chorionic gonadotropins do not reliably stimulate ovulation in the species of origin. Both of these G protein-coupled receptors are linked to adenylate cyclase and raise the intracellular levels of cAMP. There is a distinct species specificity for FSH and LH, which might lead to diminished efficacy or antibody generation in other species. hCG in particular has been shown to result in antibody production in horses (Roser et al., 1979) and has been associated with long-term or permanent infertility in some cats.

Therapeutic Uses

Apart from diagnostic application in pregnancy detection kits (i.e., hCG in early pregnancy tests for humans), gonadotropins are used in (i) promoting female and male fertility and (ii) treating cryptorchidism (Table 27.2).

The gonadotropin preparations that are available and commonly used clinically in animals are: human chorionic gonadotropin (hCG), equine chorionic gonadotropin (eCG), and follicle stimulating hormone (Follitropin-V) (Table 27.2).

Human chorionic gonadotropin

Human chorionic gonadotropin (hCG) is a gonadal stimulating hormone obtained from the urine of pregnant women. It is synthesized by syncytiotrophoblast cells of the placenta. It mainly possesses LH-like activity; therefore, it serves as a substitute for LH to promote follicle maturation, ovulation, and formation of corpus luteum. hCG is a glycoprotein and nonpituitary gonadotropin with long-lasting biological effects (>24 hours). A single injection is adequate for most reproductive uses. For example, because of its predominant LH-like activity, hCG is used to induce ovulation in the mare after an appropriate follicular size has been achieved (Wathes et al., 2003).

Uses

1) hCG is widely used for *infertility therapy*. It is used in female horses for hypogonadism due to pituitary hypofunction, and to *hasten or induce ovulation (*Samper, 2001).
2) hCG is used for the treatment of *cystic ovaries* in cows, by luteinizing the cystic structures to form a corpus luteum. The corpus luteum either regresses naturally or can be induced to regress with $PGF_{2\alpha}$ analogs (see Section Prostaglandin Analogs). Treatment recommendations are either hCG 5000 IU IV or 10,000 IU IM. Most cows respond with the establishment of an estrous cycle within 3–4 weeks.
3) eCG (400 IU) and hCG (200 IU) together make up PG600®, which is used in pigs to promote follicle development and induce estrous cycles in prepubertal gilts.
4) hCG is useful for treating male infertility due to *impotence*, particularly in the stallion. In the male,

Table 27.2 Drugs affecting reproduction in animals

Class	Preparation		Dosage
Gonadotropins			
Follicle stimulating hormone	Follitropin®-V		
	Ovagen®		
Equine chorionic gonadotropin (eCG)	PG600®	Combination of 400 IU eCG, 200 IU hCG	Pig: 1 ml PG600 IM
Human chorionic gonadotropin (hCG)	Follutein®	Injection 5,000 U and 10,000 U	Dog: 50–100 μg, SC, IV
	Chrorulon®		Cat: 25 μg, IM Horse:1,000 U, IV Cattle: 1,000–2,500 U, IV Sheep: 400–800 U, IV, IM Goat: 3,000 U, IV
Gonadorelin (synthetic GnRH)	Cystorelin®	Injection 50, 100 μg/ml	Dog: 50–100 μg, SC, IV
	Factrel®		Cat: 25 μg, IM Horse: 50 mg, SC Cattle: 100 mg, IM (100 μg)
Oxytocics			
Oxytocin	Pitocin®	Synthetic oxytocin injection 20 U/ml	Dog: 5–20 U, IM or IV once
	Syntocinon®		Cat: 2.5–5 U, IM once Pig: 10–20 U, IM Horse: 50–100 U, IV, IM, SC Cattle: 50–100 U, IV, IM, SC Sheep: 30–50 U, IV, IM, SC
Progestins			
Altrenogest	Regumate®	Solution: 2.2 mg/ml	Horse: 0.044 mg/kg/day for 15 days
Progesterone	Eazi-Breed CIDR™	Vaginal drug delivery devices	Cattle: 1.38 g for 7 days
Androgens			
Stanazolol	Vinstrol-V®	Tablets: 2 mg	Horse: 0.55 mg/kg, IM up to 4 doses once weekly
		Injection: 50 mg/ml	
Antiandrogens			
Finasteride	Proscar®	Tablets	Dog: 0.1–0.5 mg/kg, once daily for up to 16 weeks
Prostaglandins ($PGF_{2\alpha}$ agents)			
Dinoprost	Lutalyse®	Vials: 5 mg/ml	Cattle: 25 mg, IM injection Pig: 10 mg, IM injection Horse: 1 mg/100 lb body weight, IM injection Dog: 0.1–0.2 mg/kg daily for 5 days SQ (pyometra) 0.025–0.05 mg/kg q 12 h IM (termination of pregnancy) Cats: 0.1–0.25 mg/kg daily for 5 days SQ (pyometra) 0.5–1 mg/kg IM for 2 injection (termination of pregnancy)
Cloprostenol	Estrumate®	Vials: 0.25 mg/ml	Cattle, horse: 0.5 mg, IM injection

hCG stimulates the interstitial cells to produce testosterone.

5) hCG has been used for the correction of *cryptorchidism* in dogs. This practice has a low success rate in boys with congenital cryptorchidism and is considered controversial in all species (Henna et al., 2004; Thorsson et al., 2007). For details see Section Specific Uses of Reproductive Hormonal Drugs.
6) hCG may be used in sequence with eCG for the induction of pseudopregnancy in cats and fertile estrus in dogs (Stornelli et al., 2012).

Adverse reactions and side effects

Immunological reactions such as hives and anaphylaxis due to antihormone antibody production have been reported. Prolonged usage may produce loss of efficacy, which is not reliably correlated with circulating antibody titers in horses (Roser et al., 1979). Use has been associated with prolonged and permanent infertility in cats.

Dose

Veterinary preparations and dosage are listed in Table 27.2.

Equine chorionic gonadotropin (eCG)

Equine chorionic gonadotropin (eCG; formerly known as pregnant mare serum gonadotropin, PMSG) is secreted from the endometrial cups of pregnant mares in early pregnancy in order to induce secondary and accessory corpora lutea (by developing and ovulating additional follicles) and to maintain the primary corpus luteum (and thus progesterone secretion) in the mare. Its gonadotropic activity is primarily FSH-like in the horse and increases ovarian follicular growth, but it has sufficient LH-like activity to induce ovulation or luteinization. Like hCG, eCG is a glycoprotein and nonpituitary gonadotropin with long-lasting biological effects (>24 hours). A single injection is generally sufficient for marked growth of ovarian follicles (Shelton, 1990).

Uses

1) eCG is frequently used to stimulate ovarian follicular growth in the anestrous sheep or goat. It is used in combination with hCG for induction of ovulation and corpus luteum formation.
2) eCG (400 IU) and hCG (200 IU) together make up PG600®, which is used in pigs for inducing follicular growth and estrous cycles in prepubertal gilts (see Section Human Chorionic Gonadotropin).
3) eCG followed by hCG have been used successfully to induce fertile estrus in dogs (Stornelli et al., 2012).

Follicle stimulating hormone (FSH)

Two preparations are available: (i) Folltropin V® (porcine FSH), Vetrepharm, Canada; and (ii) Ovagen® (ovine FSH), ICP Bio, New Zealand. FSH is used to develop multiple follicles in donor cattle for ovulation (superovulation) and oocyte collection, and for production of multiple embryos which may be used in embryo transfer procedures (Hasler, 2002).

Prolactin

Structure and function

Prolactin is synthesized in lactotropes of the anterior pituitary, and is classified as a somatomammotropic hormone because of its structural similarity to GH (somatotropin). It is a 198-amino-acid polypeptide with three intrachain disulfide bridges. Prolactin stimulates lactation in the postpartum period. During pregnancy, prolactin secretion increases and, in concert with other hormones (e.g., estrogen, progesterone), promotes additional mammary development in preparation for milk production (Kooistra and Okkens, 2001). The secretion of prolactin during suckling maintains milk secretion by the mammary gland. It also inhibits ovarian function by suppression of the hypothalamic–pituitary–gonadal axis, and is a component of the regulatory mechanism for seasonality in horses. It is luteotrophic (supports the corpus luteum) in dogs and cats. Prolactin is secreted in a pulsatile manner (half-life, 15–20 minutes).

Mechanism

Prolactin, acting via the prolactin receptor, plays an important role in inducing growth and differentiation of the ductal and lobuloalveolar epithelium; lactation does not occur in the absence of this hormone.

Regulation

Prolactin is unique among the anterior pituitary hormones in that hypothalamic regulation inhibits its secretion. The major regulator of prolactin secretion is *dopamine* (also known as *prolactin inhibiting hormone*, PIH), which is released by tuberoinfundibular neurons and activates the D_2 receptors on lactotropes to inhibit secretion of prolactin. Hence, dopamine agonists or antagonists are expected to affect prolactin release (such as cabergoline and metoclopramide, respectively). Prolactin is the only anterior pituitary hormone for which a unique stimulatory releasing factor has not been identified. Thyrotropin releasing hormone (TRH) can stimulate prolactin release, but its physiological role is unclear. Prolactin is not under feedback control by peripheral hormones.

Therapeutic Uses

Prolactin has no therapeutic uses. Milk production in cattle does not appear to be limited by the circulating prolactin.

Other drugs that affect prolactin

Metoclopramide (Reglan®) is used as an antiemetic in small animals and to stimulate stomach emptying and small intestinal motility in small and large animals via an antagonism of dopamine action. Metoclopramide induces a transient increase of prolactin. Women at risk for developing mammary gland carcinoma are advised to avoid use of metoclopramide, but such a risk factor has not been identified for animals. Efficacy for treatment of agalactia in animals has not been determined, yet. Metoclopramide is discussed in more detail in Chapter 46.

Domperidone (Motilium®, Equidone®) has been available as a tablet for people outside the USA to stimulate gastrointestinal motility and its mechanism of action (also a dopamine antagonist) is similar to metoclopramide. A difference between metoclopramide and domperidone is that the latter does not cross the blood–brain barrier. Therefore, adverse CNS effects with domperidone are not as much of a problem in horses compared with metoclopramide. Fescue toxicosis is caused by a fungus that produces a toxin (an ergot alkaloid = a dopamine agonist) that induces reproductive problems (e.g., decreased lactation or agalactia) associated with decreased prolactin levels in horses. There have been studies to investigate the use of domperidone (which acts to stimulate prolactin secretion via dopamine antagonism) to increase lactation in horses suffering from agalactia associated with fescue toxicity. Equidone oral gel (11%) is FDA approved for prevention of fescue toxicosis and related agalactia in periparturient mares. It is to be administered for 10 days prior to foaling. The recommended dose to be administered to horses is 1.1 mg/kg, daily PO, starting 10 days before the scheduled foaling date. Administration should continue until foaling. If adequate milk production does not occur after foaling, treatment should continue for 5 additional days. Because of drug interactions, domperidone should not be administered with stomach antacids such as omeprazole, cimetidine, or antacids.

Domperidone and sulpiride, another dopamine antagonist, have been used in horses to advance the first ovulation during deep anestrus. In one comparative trial, sulpiride was slightly more effective than domperidone for this purpose (Mari et al., 2009).

Therapeutic uses of drugs that inhibit prolactin are limited primarily to domestic dogs and cats. In these species, unique physiological differences make “antiprolactin” drugs desirable for the purpose of pregnancy termination, treatment of pseudopregnancy, pyometra, and estrus induction. A series of trials have demonstrated that either bromocryptine or cabergoline result in luteolysis and can effectively terminate pregnancy in the second half of pregnancy (Onclin et al., 1995). Use of a dopamine agonist in combination with prostaglandin substantially reduces the dose necessary for clinical efficacy and prevents most side effects resulting from prostaglandin treatment in these species (Onclin et al., 1995). In addition, bromocryptine and cabergoline have been shown to induce fertile estrus cycles in anestrus dogs at least 30 days after the end of diestrus (Verstegen et al., 1999). In a more recent trial, cabergoline was more effective than eCG (Nak et al., 2012).

Oxytocin

Structure

Oxytocin is a cyclic nonapeptide that is structurally similar to vasopressin. It is synthesized as a large precursor molecule in cell bodies of magnocellular neurons located in the paraventricular nucleus (PVN) in the hypothalamus. It is packaged as an oxytocin–neurophysin complex, and secreted from nerve endings that terminate primarily in the posterior pituitary gland. Stimuli for oxytocin secretion include sensory stimuli arising from the cervix and vagina and from suckling of the teats of the mammary gland. Oxytocin is under tonic inhibition (by GABAergic synapses) of the PVN neurons in the hypothalamus. Disinhibition of such control results in rapid firing of oxytocin-containing neurons leading to oxytocin release.

Functions

The two principal targets of oxytocin are the uterus and mammary gland.

Uterus Oxytocin stimulates both the frequency and force of uterine (myometrial smooth muscle) contraction. These effects are highly dependent on estrogen and the immature uterus is quite resistant to the effects of oxytocin. Progesterone antagonizes the stimulant effect of oxytocin, and the decline in progesterone seen in late pregnancy may play an important role in the normal initiation of parturition.

Mammary gland Oxytocin plays an important physiological role in milk ejection. It induces contraction of smooth muscle, most importantly of the myoepithelial cells of the mammary gland, which result in milk ejection. Suckling is the main stimulus that causes oxytocin secretion (Goodman and Grosvenor, 1983).

Oxytocin is also found in birds, fish, and reptiles. In these species, it also has a strong osmoregulatory (antidiuretic hormone or vasopressin-like) effect.

Mechanism of Action

Oxytocin acts via specific G protein-coupled membrane receptors, which upon activation lead to generation of inositol triphosphate (IP_3) from phosphoinositide hydrolysis. IP_3 mobilizes intracellular Ca^{2+} and consequently depolarization–contraction of smooth muscle tissues containing oxytocin receptors.

Clinical Uses

Oxytocin (Pitocin®, Syntocinon® or generic veterinary formulations, e.g., Oxoject®) is primarily used in labor induction and milk letdown (Jeffcott and Rossdale, 1977). Studies also indicate uses in endometritis treatment and for disruption of luteolysis in mares (see below in this section). Oxytocin, originally extracted from animal posterior pituitaries, is now chemically synthesized. The dosage of oxytocin is listed in Table 27.2.

1) Induction of labor: Oxytocin is widely used in small, large, and exotic animal practice to assist parturition (uterine inertia), to induce early or timed parturition, and to encourage postpartum uterine involution and emptying. To induce labor, it is administered intramuscularly or intravenously (Macpherson et al., 1997; Gonzales-Lozano et al., 2009). Oxytocin is used after correction of uterine prolapse in order to promote uterine contractility and involution, preventing reprolapse.
2) Milk letdown. Oxytocin is used empirically to stimulate milk letdown. Oxytocin spray is used intranasally to stimulate milk letdown 5–10 minutes before nursing. However, efficacy of either injectable or intranasal oxytocin has not been established in most domestic species.
3) Persistent postmating endometritis: Oxytocin is a treatment for mating-induced persistent endometritis in the mare; it aids myometrial contractions to clear the uterus of debris following mating (Troedsson, 1999).
4) Inhibition of cyclicity: Evidence has demonstrated that oxytocin administered to mares during early diestrus disrupts the luteolytic event and prevents cyclicity in approximately 60–70% of cases (Vanderwall et al., 2007). Interestingly, the long-acting synthetic analog carbetocin did not have the same clinical effect (Bare et al., 2013). The mechanism of action for the luteal maintenance appears to be unrelated to oxytocin-receptor expression in the uterus, but is associated with decreased prostaglandin production (Keith et al., 2013).

Adverse Reactions and Side Effects

Toxicity is uncommon with oxytocin. Overdose or repeated dosing can lead to painful contractions and even uterine rupture and fetal death.

Prostaglandin Analogs

Prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) is a luteolytic agent produced by the endometrium. In domestic herbivores, it is released in late diestrus in the cycling animal. It is released near term in all pregnant animals (Kindahl et al., 1981). $PGF_{2\alpha}$ mediates a decrease in circulating progesterone via luteolysis (corpus luteum regression) at the end of the cycle and pregnancy. $PGF_{2\alpha}$ acts via the activation of G-protein-coupled receptor linked to IP_3-Ca^{2+}-protein kinase C pathway, which leads to decreased steroidogenesis and luteolysis. There are several prostaglandin analogs (see Tables 27.1 and 27.2) that are used are widely used to regulate estrous cycles, induce abortion, and induce parturition in animals (Schultz and Copeland, 1981).

Uses

1) Estrous synchronization: Dinoprost ($PGF_{2\alpha}$) and its analogs are used for estrous synchronization. They cause premature luteolysis, thus decreasing estrous cycle length and thereby hastening the onset of estrus. It can achieve reliable luteolytic activity after maturation of the corpus luteum is complete (approximately day 5 in horses and ruminants) (Oxender et al., 1975). A study has also demonstrated that $PGF_{2\alpha}$ has "antiluteogenic" properties, and that repeated administration can prevent progesterone from rising after ovulation in the mare (Coffman et al., 2013). Used strategically, in most large animal species except the pig, $PGF_{2\alpha,}$ alone or in conjunction with progesterone/progestin treatment and withdrawal (see Section Progestins) can be used to synchronize estrus in groups of animals. It can also be used in conjunction with GnRH for timed AI or embryo transfer (see Section Gonadorelin).
2) $PGF_{2\alpha}$ is used to induce abortion and parturition in the bitch (Romagnoli et al., 1991). Prostaglandins are effective at inducing luteolysis early in diestrus (Olson et al., 1992; Onclin and Verstegen, 1996). However, the high doses of prostaglandin required in early pregnancy are associated with substantial clinical side effects, including emesis, diarrhea, and cramping. Further, pregnancy may be maintained even after documented luteolysis at this stage (Olson et al., 1992; Feldman et al., 1993). For details for the use of $PGF_{2\alpha}$ to terminate pregnancy see Section Specific Uses of Reproductive Hormonal Drugs.
3) In the cow, $PGF_{2\alpha}$ is used to induce luteolysis and stimulate uterine contractions to facilitate placental delivery (Milvae and Hansel, 1983; Gross et al., 1986).
4) In the mare, $PGF_{2\alpha}$ is frequently used to terminate diestrus and facilitate rapid breeding and to treat mating-induced persistent endometritis. However, studies suggest that prostaglandin use

near ovulation may diminish fertility, calling into question its widespread use (Troedsson et al., 2001; Cuervo-Arango and Newcombe, 2010).

5) In the bitch, $PGF_{2\alpha}$ is used to treat uterine infections via luteolytic and ecbolic effects (see point 2 in this section).

Adverse Reactions and Side Effects

$PGF_{2\alpha}$ causes increased smooth muscle tone, resulting in diarrhea, abdominal discomfort, bronchoconstriction, and increase in blood pressure. In small animals, other side effects include vomiting. Induction of abortion may cause retained placenta.

Dinoprost should not be administered intravenously. It should never be administered to pregnant animals, unless abortion is a desired outcome.

Veterinarians and their assistants should use caution when handling this drug. It should not be handled by pregnant women. Absorption through the skin is possible. People with respiratory problems also should not handle dinoprost.

Reproductive Steroid Hormones (Estrogens, Progesterone, Androgens)

A wide range of steroid hormonal treatment programs have been developed to regulate or induce estrous cycles in small and large animals for breeding purposes. Programs structured to provide increased levels of progesterone, estradiol, and related steroids at the appropriate times, leading to ovulation and pregnancy, have been commonly used in theriogenology (Day, 2004). Androgens are included for discussion in view of their therapeutic uses as anabolic steroid hormones. The three distinct classes of reproductive steroid hormones (estrogens, progestins, and androgens) are discussed here, including their general mechanism of action, pharmaceutical preparations, and therapeutic applications in veterinary medicine.

Mechanism of Steroid Action

The mechanism of action of steroid hormones (estrogens, progestins, and androgens) involves binding to intracellular steroid receptors, which mediate most biological actions of steroids. These steroid receptors are located *inside* the cell, in the nucleus or cytoplasm. Steroid hormones diffuse readily across the cell membrane and bind to intracellular receptors located in the cytoplasm, which are then translocated to the nucleus, or already located in the nucleus. The hormone–receptor complex interacts directly and specifically with sites on the DNA (in the nucleus) called *hormone response elements* (HRE), and act as transcription factors to activate or inhibit gene expression (*transcription*) of the nearby genes. The resulting mRNAs are translated into specific proteins, which brings about a change in the metabolism or other functions of the cell. In contrast to hormones acting through membrane receptors that act rapidly within few minutes or less, the biological effects of steroid hormones generally take longer to occur (hours to days) because of the complex signaling cascade.

A brief description of some important pharmacological steroidal agents used in veterinary practice is given in Table 27.2.

Estrogens

The major ovarian estrogen in females is estradiol. Other estrogens include estrone and estriol, which is produced by the placenta. Estrogens are transported in the blood by binding to sex hormone-binding globulin (SHBG). Estradiol is active by the oral route for pharmacotherapy, but has low bioavailability because of extensive first-pass hepatic metabolism. Therefore, for some treatments injectable preparations are used. For oral administration, semisynthetic derivatives (ethinyl estradiol) or synthetic estrogens (mestranol) or nonsteroidal derivatives (diethyl stilbosterol, DES) have been developed for clinical use.

Therapeutic Uses

Estrogen is essential for normal development of secondary sexual phenotype and reproductive behavior in females. Estrogen modifies serum protein levels and reduces bone resorption. It is also an effective feedback suppressor of pituitary LH and FSH secretion. Estrogens may be useful in the treatment of the following conditions: hypogonadism; postmenopausal symptoms (humans); contraception/ elective pregnancy termination; persistent vaginitis in prepubertally spayed bitches; benign prostatic hyperplasia/ carcinoma of prostate (canine).

Adverse reactions and side effects

The most common toxicity in humans associated with chronic estrogen usage includes breast cancer, endometrial hyperplasia, breakthrough bleeding, and uterine carcinoma. Toxicity recognized in domestic carnivores includes bone marrow suppression, increased risk of pyometra, tendon laxity, and ventral alopecia.

Veterinary Uses

Estrogens are not widely used in veterinary medicine, especially in food animals due to the concerns about drug residues in meat for human consumption. The following estrogen preparations have been used in veterinary medicine. *Estradiol benzoate* and other estrogens have been used for the purpose of estrus induction and to prevent implantation of embryos in bitches (Kutzler, 2005; Sutton et al., 1997). In cattle, they have been suggested for the treatment of postpartum cow to decrease uterine infection and to hasten uterine involution.

Diethylstilbestrol (DES, Stilboestrol®) is a nonsteroidal estrogenic agent used in the management of estrogen-responsive urinary incontinence and persistent vaginitis in spayed animals, and for estrus induction and to prevent implantation of embryos in bitches. It has been used in the treatment of benign prostatic hyperplasia and perianal gland adenoma in dogs (Kutzler, 2005; Hill et al., 2012; Sutton et al., 1997; Niżański, 2014). *It should be noted that the use of estrogens for many of these purposes is controversial and that better alternatives may be available.*

Progestins

Progesterone is the major progestin in humans and animals. Progesterone is rapidly metabolized in the liver and therefore has a very low bioavailability and a short half-life. Synthetic progestins altrenogest (allyl-trenbolone, Regumate®) and melengestrol acetate (MGA) are widely used in veterinary practice to induce long-lasting ovarian suppression and synchronization of estrous cycle following progestin withdrawal in small and large animals. Progestins act on progesterone receptors in the hypothalamus/ pituitary, increasing the negative feedback and decreasing FSH and LH output. The withdrawal of progestin therapy initiates a new estrous cycle and ovulation.

Adverse Reactions, Side Effects, and Precautions

Humans handling progestin formulations should wear gloves and avoid contact, as for example altrenogest can be absorbed through intact skin. Contraindications for the use of progestins can be a history of endometritis or pyometra. There might also be an increased risk for diabetes mellitus.

The following preparations of natural progesterone or synthetic progestins are most widely used in veterinary medicine.

Altrenogest

Altrenogest (Regumate®), also known as *allyl-trenbolone*, is a synthetic, orally active progestin indicated for controlling the estrous cycle of the mare and pig (see Figure 27.1).

Altrenogest is indicated to suppress estrus in mares to allow a more predictable occurrence of estrus following withdrawal of the drug (Davis et al., 1985; Shimatsu et al., 2004). Altrenogest (0.044 mg/kg, PO) is recommended for 15 days to suppress estrus and allow for a predictable occurrence of estrus in mares. This effect is enhanced by administration of both a progestin and an estrogen. In addition, altrenogest and other progestins have been used to advance the first ovulation of the breeding season. However, the use of Regumate is controversial and some studies suggest altrenogest alone has a limited ability to shorten the transition period. Altrenogest is not effective during winter anestrus. Ovulation occurs 9–11 days after altrenogest therapy. Use of a prostaglandin ($PGF_{2\alpha}$) immediately following altrenogest withdrawal will induce estrus. Generally, altrenogest may be helpful to control the equine estrous cycle, but it has not always been able to exert predictable control over the estrous cycle of the mare (Lofstedt and Patel, 1989). Altrenogest can also be used in synchronizing estrus in the gilt (Davis et al., 1985). Swine producers are interested in synchronizing estrus in gilts to reduce the number of replacement gilts and for optimizing breeding by AI. Altrenogest is given to gilts at 15–20 mg daily for 18 days, which results in 95% expression of estrus 4–7 days after altrenogest withdrawal. Research has demonstrated that altrenogest administration may increase litter size in a subpopulation of sows (van Leeuwen et al., 2011).

In addition, altrenogest is widely used in mares for the prevention of pregnancy loss (Daels et al., 1991, 1996). A "double-dose" of altrenogest (0.088 mg/kg) can be used in pregnancy to minimize the abortion in mares suspected of hypoluteoidism or which experience either prostaglandin or endotoxin exposure, or for mares diagnosed with placentitis (Bailey et al., 2010). Although altrenogest is considered safe in pregnant mares, some research suggests it may be associated with fetal or neonatal abnormalities, or with slight delays in parturition (Neuhauser et al., 2009).

Melengestrol Acetate

Melengestrol acetate (MGA) is a progestin based, feed-additive system to synchronize estrous in cattle. This product is indicated for use in estrus suppression in feedlot heifers and has been used with increased frequency to synchronize breeding females. MGA can be fed at a rate of 0.5 mg per head per day to suppress estrus. Once MGA is removed from the feed, females will begin cycling within a few (normally 2 to 3) days. Briefly, the MGA program consists of providing MGA at the prescribed level in a feed product the cattle will consume, once daily for 11 to 14 days. After removal of the MGA from the feed, estrus follows after 48 to 72 hours. At this point, breeding can begin with bulls or via artificial insemination. MGA is a simple treatment, but is generally less efficient than other estrous synchronization products.

CIDR® – Progesterone-Containing Controlled Internal Drug Release Intravaginal Device

Several CIDR (Controlled Internal Drug Release) intravaginal progesterone-releasing devices are marketed for

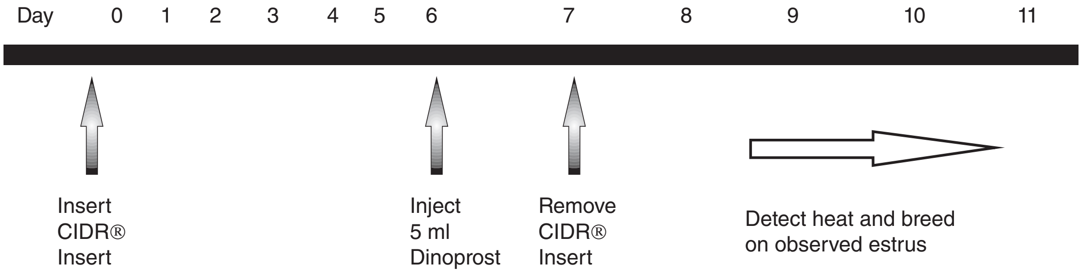

Figure 27.2 Eazi-Bred^{TM} CIDR protocol for synchronization of estrus in cattle. The Eazi-Breed CIDR for cattle consists of 1.38 g progesterone releasing device for vaginal insertion in breeding programs. CIDR, controlled internal drug release.

cattle (Eazi-Breed), sheep (CIDR-S^{TM}), and goats (CIDR-G^{TM}). The main objective of these products is synchronization of estrus, to improve the timing and efficiency of breeding programs of both dairy and beef breeds of cattle (Yavas and Walton, 2000; Lamb et al., 2010; Wiltbank et al., 2011). The Eazi-Breed CIDR contains 1.38 g progesterone in silicon molded over a nylon spine. These inserts are to be administered intravaginally, one per animal, in dairy heifers for breeding. It releases progesterone during the 7-day treatment period (Figure 27.2). To induce definitive synchronization, an injection of a prostaglandin dinoprost tromethamine (Lutalyse®) is given to all heifers one day before insert removal. Removal of the insert on treatment day 7 results in a decline in plasma progesterone, triggering estrus within 3 days.

Androgens and Finasteride

Testosterone

Testosterone is the principal circulating androgen in males. It is secreted by the Leydig cells of the testes in response to LH from the pituitary gland. Testosterone regulates the male reproductive system by binding to the androgen receptor present especially in reproductive tissues, muscle, and fat. It is particularly responsible for normal male sexual differentiation. Some physiological effects of testosterone are mediated by conversion to dihydrotestosterone, a more potent androgen than testosterone (Figure 27.3). Testosterone also is converted to estradiol by Sertoli cells of testis in the adult. Several analogs of testosterone that possess greater *anabolic* (protein building) than *androgenic* (male sexual) effects have been synthesized, which are known as *anabolic steroids***.** These include *nandrolone, stanazolol, oxymethalone,* and others. The major indication for the use of anabolic steroids is in equine medicine to increase athletic performance. Anabolic steroids increase muscle size, strength, and increase red blood cell production. Excretion of urea nitrogen is also reduced ("positive nitrogen balance"). Many of the anabolic steroids are tightly controlled in horses involved in competition, and care should be exercised to ensure that their administration falls within the guidelines of the governing organization in question (Soma, 2007, 2008). Furthermore, administration of androgens or anabolic steroids should be performed with caution in potential breeding animals due to the known negative feedback effects on the ovarian and spermatogenic cycles.

Therapeutic uses There are only few clinical evaluations of testosterone for therapeutic use in veterinary medicine.

Anabolic Steroids

Anabolic steroids are controlled substances that predominantly produce greater anabolic than androgenic effects, and, as described in Section Stanazolol, Nandrolone, Boldenone Undecylenate, Trenbolone Acetate, are used in equine practice to increase athletic performance. In addition, these agents have been used in the treatment of aplastic anemia (dogs and cats), myeloproliferative disease, and lymphoma accompanied by nonregenerative anemia. They increase myelopoiesis, stimulate the production of erythropoietin, and increase

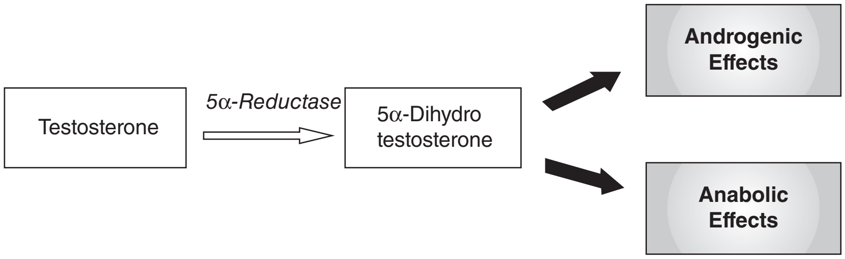

Figure 27.3 Metabolism and major effects of testosterone. Testosterone is converted in several organs to dihydrotestosterone (DHT), which is the active hormone in those tissues. Testosterone and DHT produce both androgenic and anabolic actions.

production of erythrocytes. They stimulate appetite, promote a positive nitrogen balance, and muscle calcium levels (Brower, 1993). Several weeks to months may be required for a positive response to be seen, and even with this prolonged therapy only one-third of dogs and cats show a positive erythropoietic response to anabolic steroids. Anabolic steroids bind to androgen receptors present especially in reproductive tissue, muscle, and fat. The ratio of anabolic ("body-building") effects to androgenic ("virilizing") effects may differ among the members of this class of drugs, but in practice all agents possess both properties to some degree (Figure 27.3).

Stanazolol, Nandrolone, Boldenone Undecylenate, Trenbolone Acetate

Stanazolol (Winstrol-V$^{®}$) is an anabolic steroid with strong anabolic and weak androgenic activity. It is potentially useful as an adjunct to the management of catabolic disease states (Cowan et al., 1997). It has been recommended to stimulate erythropoiesis, arouse appetite, promote weight gain, and increase strength and vitality. However, the efficacy of stanazolol is controversial and requires 3–6 months' treatment before a positive change may be seen. Stanazolol is most commonly used in horses to enhance athletic performance. Stanazolol is potentially hepatotoxic. Stanazolol may produce weight gain, sodium and water retention and, exacerbate azotemia. It may promote hypercalcemia, hyperphosphatemia, and hyperkalemia.

Nandrolone (also referred to as 19-nortestosterone) is also a potent synthetic anabolic androgenic steroid. Nandrolone is useful in the treatment of certain rare forms of aplastic anemia, which are or may be responsive to anabolic androgens. It has been used in some cases to counteract catabolic states, for example after major trauma or strenuous physical exercise (Hyyppa, 2001).

Boldenone (Equipoise$^{®}$) is a steroid ester anabolic agent. It is used, primarily in horses, to improve nitrogen balance, reduce overexertion associated with exercise, and improve training. It may also improve appetite and improve weight gain when used with a well-balanced diet. Boldenone is a long-lasting agent and effects may persist for 6 weeks after an intramuscular injection.

Trenbolone acetate is not used therapeutically, but is used as an implant (often combined with estradiol) approved for use as a growth promoter for beef cattle. Although these implants have an important economic benefit to the beef cattle industry (Duckett and Pratt, 2014), research indicates a possible risk of trenbolone acetate as an endocrine disrupting substance in the environment (Qu et al., 2013).

Adverse Reactions and Side Effects

After administration of androgens increased masculine effects and possibly aggressiveness are common. In human, the use of some anabolic steroids is associated with hepatic toxicity.

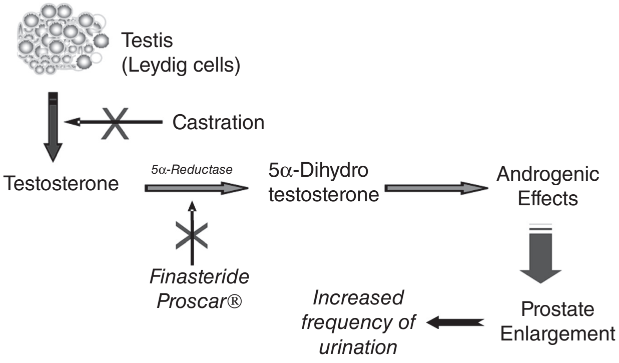

Figure 27.4 Treatment options for benign prostatic hypertrophy. Reduction of androgen effects is an important therapeutic goal for benign prostatic hypertrophy (BPH). Inhibition of dihydrotestosterone produced by finasteride is a key pharmacotherapy in dogs affected by BPH.

Anabolic steroids are contraindicated in dogs with benign prostatic hypertrophy. Anabolic steroids may produce carcinogenicity and teratogenicity.

Finasteride

Finasteride (Proscar$^{®}$) is an irreversible 5α-reductase inhibitor that blocks the conversion of testosterone to 5α-dihydrotestosterone, a potent androgen receptor agonist (Figure 27.4). Testosterone itself interacts weakly with the androgen receptor. Therefore, most of the biological effects of testosterone have been attributed to the synthesis of endogenous 5α-dihydrotestosterone. In the prostate gland, 5α-dihydrotestosterone has been implicated to cause benign prostatic hypertrophy.

Uses

Finasteride is the drug of choice for benign prostatic hypertrophy in dogs. Finasteride induces prostatic involution by apoptosis in dogs with spontaneous benign prostatic hypertrophy (Sirinarumitr et al., 2002). Finasteride is highly effective in benign prostatic hypertrophy cases. Finasteride has not proven valuable in prostatic carcinoma.

Dose

Finasteride (0.1 to 0.5 mg/kg, PO once daily) therapy for 16 weeks may reduce prostate size in canine prostatic hypertrophy.

Adverse Reactions and Side Effects

The major potential side effect is *impotence*. Finasteride, however, did not affect semen quality or serum testosterone concentrations in experimental studies in dogs.

Specific Uses of Reproductive Hormonal Drugs

Superovulation

Cattle may be induced to ovulate multiple follicles (superovulation) so that embryos can be transferred to multiple recipient animals to increase the number of progeny. In cattle, superovulation results in about 10 ovulations, compared to the normal, single ovulation. Superovulation, on the average, results in about six usable embryos. The ideal response is five to 12 embryos from one-third of the donors. The superovulation injection program of donor cows is initiated between day 9 and 14 of the estrous cycle, with FSH given over 4 days and $PGF_{2\alpha}$ given on days 3 and 4 of treatment. In the case of goats and sheep, the drug regimen for superovulation depends upon the reproductive status. During the breeding season, $PGF_{2\alpha}$ is used to mediate luteolysis, and gonadotropins are given to increase the ovulatory rate. Dairy goats were superovulated successfully during the breeding season by placement of an intravaginal sponge (medroxyprogesterone acetate, 60 mg) for 11 days, 125 μg cloprostenol IM on days 1 and 9 of sponge treatment, and twice daily injections of FSH-P (2.5 mg) IM for 3 days beginning on day 9 of sponge treatment (Thompson, 2001). The anestrous animal is given a progestin followed by gonadotropin treatment.

Pseudopregnancy

For treatment of queen (female cat) in heat, animals may be treated with GnRH or hCG. These animals are induced ovulators and in the absence of the mating stimulus, ovulation and corpus luteum formation must be induced with GnRH or hCG, as described in Section Gonadotropin-Releasing Hormone, Gonadorelin, and Gonadotropins, to prevent repeated estrus periods. In some rodents (rats and mice), a state of pseudopregnancy associated with prolonged high serum progesterone levels can be induced by sequential administration of eCG and hCG elevated progesterone (Reddy et al., 2001). This sequential regimen may be useful in transgenic mice breeding programs.

In contrast, in dogs pseudopregnancy refers to inappropriate mammary development and mothering behavior in nonpregnant bitches. This condition is related to the normal physiology of the bitch and can often be managed conservatively by increasing the animal's activity and reducing stimuli that encourage maternal behavior. However, recent data have suggested that bitches experiencing repeated and severe pseudopregnancy may be at increased risk for pyometra or mammary tumors. Clinical resolution of pseudopregnancy can be achieved by administration of a dopamine agonist such as cabergoline during late diestrus.

Parturition

Parturition may be induced as an elective procedure in many species. The reasons for induced parturition include: (i) enhancing the ability of managers to attend parturition, (ii) attempting to save either the neonate or dam in cases of severe illness, and (iii) synchronize parturition for production purposes.

In cattle, dexamethasone (20–30 mg) or flumethasone (8–10 mg) IM is 80–90% effective in parturition induction, with calving occurring 24–72 hours posttreatment. Calving may be induced with $PGF_{2\alpha}$ (25–30 mg) or cloprostenol (500 μg) IM with results similar to that found with glucocorticoids. The interval from injection to calving is 24–72 hours. A combination of treatments with dexamethasone and cloprostenol has resulted in a shorter interval from treatment to delivery and a greater percentage induced compared to either drug alone or two injections of cloprostenol. The optimal farrowing response to $PGF_{2\alpha}$ is achieved by administration within 2 days of normal delivery for a herd. Induction of parturition in the mare is considered controversial and associated with higher complication rates than other large animal species. A combination of prostaglandin E and sequential doses of 15 IU of oxytocin increased success rates, compared to oxytocin alone (Rigby et al., 1998). Subsequently, low doses of oxytocin (2.5–3.5 IU) have been shown to be safer. A small dose of oxytocin given once daily fails to induce parturition until after fetal maturation, while resulting in foaling within 120 minutes in 68–95% of mares with mature foals (Camillo et al., 2000; Villani and Romano, 2008). Alternately, precocious fetal maturation has been successfully induced using dexamethasone (100 mg q 24 h for 3 days; Ousey, 2011).

Termination of Pregnancy (Abortion)

Pregnancy termination is one of the most common "reproductive" requests from dog and cat owners because of mismating or other reasons. Pharmacological agents are available that can prevent or terminate pregnancy (Eilts, 2002). Estrogens can be given during estrus to prevent pregnancy (Sutton et al., 1997); however, their use is controversial and should be avoided if possible. A pregnancy examination should be performed before any drug is given to terminate pregnancy. If a dog is known to be pregnant, multiple doses of natural prostaglandins (25–250 μg/kg) or synthetic prostaglandins (cloprostenol, 1–5 μg/kg) can be used throughout pregnancy. However, higher doses of prostaglandins are associated with substantial clinical side effects, including vomiting, diarrhea, lethargy, and cramping. Thus hospitalization and careful monitoring of animals are recommended to control side effects, which tend to be more severe early and diminish during the course of treatment. Side effects may be minimized by using low doses after day 30 (30–50 μg/kg, three to four times daily for 4–11 days) (Olson et al., 1992), or by starting with a lower dose and gradually increasing it (30–50 μg/kg, increased to 100–200 μg/kg). Additional complications associated with prostaglandin use for abortion are incomplete luteolysis and treatment failure or mummification of dead pups/kittens. Multiple doses of inhibitors of prolactin secretion (cabergoline, bromocriptine) or dexamethasone are associated with fewer side effects, but are not effective in the first half of gestation. Combined protocols of prostaglandin and prolactin inhibitors are also effective at terminating pregnancy beginning day 25 post-LH (Onclin et al., 1995). Progesterone blockers such as mifepristone and aglepristone are effective, but not available in the USA. Other drugs, such as the isoquinolones and progesterone synthesis inhibitor epostane, are available outside of the United States and appear to be very effective at terminating pregnancy.

Cryptorchidism

Cryptorchidism (dog) is the failure of one or both testes to be present in the scrotum by 6–8 weeks of age. The testes migrate from the caudal pole of the kidney to the scrotum via guidance from the gubernaculum testis. At birth, the testes in the dog are usually within the abdomen near the internal inguinal ring. The testes move through the inguinal canal and are in the scrotum by 10–14 days of age. Because this condition can have a genetic basis, dogs with this condition should not be used for breeding purposes. The most common method of treatment is a series of injections of hCG. Dogs younger than 16 weeks of age are the best candidates. The IM injection of 100–1000 IU hCG four times in a 2-week period is expected to result in testicular descent in a majority of dogs.

However, success rates are variable and cryptorchidism is typically not treated and they are not encouraged to enter the genetic pool (Goericke-Pesch, 2010). Likewise, in other species (cattle, sheep, goats, horses), pharmacological treatment of cryptorchidism is generally not supported.

Benign Prostatic Hypertrophy

Benign prostatic hypertrophy (BPH) is a spontaneous and age-related disorder of intact male dogs, which occurs in more than 80% male dogs over 5 years of age. BPH is associated with clinical signs of sanguineous prostatic fluid, constipation, and dysuria. BPH is linked to the androgenic activity of dihydrotestosterone, metabolized locally from testosterone, on accessory sex glands (enlargement of prostate gland). BPH can be identified by the signs such as increased frequency of urination, constipation, or blood in urine. BPH often occurs concurrently with prostatic infection, abscessation, cysts, and neoplasia in the intact dog. The treatment of choice is castration or antiandrogenic agents such as finasteride, a 5α-reductase inhibitor, or flutamide, an androgen receptor antagonist (Iguer-Ouada and Verstegen, 1997; Johnston et al., 2000). Occasionally, progestins are used. However, these are associated with decreased libido and fertility (Niżański et al., 2014).

Thyroid Hormone and Antithyroid Drugs

Duncan C. Ferguson

Introduction

Hypothyroidism

Hypothyroidism is the most common endocrinopathy of the dog as a result of the breed-associated incidence of lymphocytic thyroiditis. Clear syndromes of congenital hypothyroidism are recognized in the neonatal horse, but the incidence and pathogenesis in the adult horse is less understood. Spontaneous hypothyroidism in the cat and other domestic species is most commonly associated with congenital disease or following thyroidectomy. Less commonly, hypothyroidism can be caused by iodine deficiency or by the ingestion of goitrogenic substances in the environment or food; goitrogenic substances are compounds that interfere with thyroid hormone synthesis by the thyroid gland.

Clinical signs of hypothyroidism common to most species generally reflect the reduction in basal metabolic rate of the body and include lethargy, mental depression, weakness, inability to train, and/or nonpruritic hair loss (Ferguson, 1989a, 1993; Ferguson and Hoenig, 1991b; Ferguson et al., 1992; Peterson and Ferguson, 1990; Feldman and Nelson, 2004a).

Hyperthyroidism

Hyperthyroidism is now the most common endocrine disorder in the cat, and is only occasionally seen in other domestic species. Hyperthyroidism or thyrotoxicosis is caused by excessive concentrations of the circulating thyroid hormones, thyroxine (T_4) and triiodothyronine (T_3), most commonly the result of hyperplastic or benign adenomatous malignant thyroid glands in cats and adenocarcinomas in dogs. Hyperthyroidism occurs most frequently in middle-aged to geriatric cats and discussion of therapeutic agents will focus on those used in this species. The most common clinical signs associated with hyperthyroidism, which can be directly related to thyroid hormone excess, are weight loss in spite of ravenous appetite, hyperactivity, polydipsia, polyuria, diarrhea, intermittent fever, vomiting, and symptoms of cardiovascular disease such as tachycardia and dyspnea. Often the cats shed excessive amounts of hair or the coat may be matted. Rarely, hyperthyroid cats present in a way similar to what has been called "apathetic hyperthyroidism"; the cats are lethargic and often anorectic, perhaps representing an end-stage form of the disease (Feldman and Nelson, 2004b; Ferguson and Hoenig, 1991a; Peterson and Ferguson, 1990). Therapy focuses upon either definitive treatments such as radioiodide and thyroidectomy, or, as discussed below, the administration of drugs that reduce the synthesis, secretion, metabolism, and/or action of thyroid hormone.

Thyroid Physiology

Iodine Metabolism

Thyroid hormones are the only iodinated organic compounds in the body with the two major secretory products of the thyroid gland, thyroxine ($\text{L-}T_4$) and 3,5,3′-triiodothyronine ($\text{L-}T_3$) containing 65% and 59% iodine, respectively. The minimum iodine requirement of most animals is unknown, but the daily amount needed in the ration to prevent goiter in all animals is generally accepted to be about 1 μg/kg body weight. The daily recommended amount of iodine in the dog is 15 μg/kg and while it has not been carefully studied in the cat, it is believed to be about 100 μg/cat/day. Commercial cat foods have been shown to be quite variable in the amount of iodide provided, probably a result of the variable amount of seafood used to create the diet. Indeed, dietary iodide has been shown to be inversely related to free T_4 concentrations (Tarttellin and Ford, 1994). Also, a review has questioned the adequacy of iodide in commercial cat diets before 2006, suggesting that the increased incidence of feline hyperthyroidism might have been associated with iodide deficiency (Edinboro et al., 2010). Although true nutrient requirements for this micronutrient are not well established, most commercial dog and

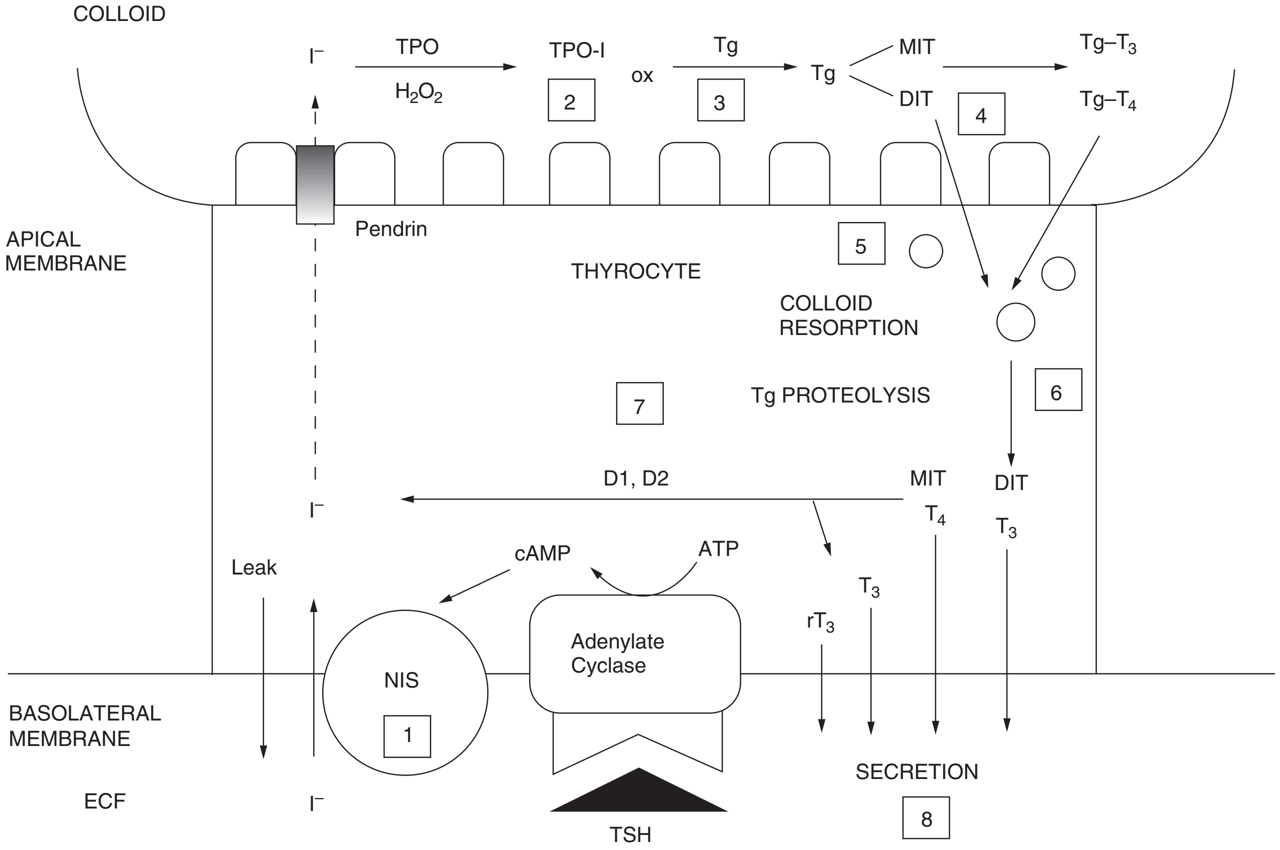

Figure 28.1 Thyrotropin (thyroid-stimulating hormone, TSH)-stimulated iodide uptake and organification by the thyrocyte. **Step 1:** Inorganic iodide (I^-) is actively translocated by the sodium–iodide symporter (NIS), using the Na^+ gradient established by the Na^+K^+-ATPase. NIS is stimulated directly by the G protein-coupled TSH receptor, and is influenced by availability of iodide, being stimulated by iodide insufficiency and suppressed by excess iodide. After diffusing to the apical or brush border membrane, the pendrin protein carries it into the lumen of the colloid. **Steps 2 and 3 Oxidation and organification:** Iodide is oxidized by the thyroid peroxidase enzyme (TPO) (Step 2) and added to a tyrosine residue of preformed thyroglobulin (Tg) (Step 3) to form monoiodotyrosine (MIT) and diiodotyrosin (DIT). **Step 4 Coupling:** The MIT and DIT residues on Tg couple to form T_3, and two DIT residues couple to form T_4. Steps 2–4 are sensitive to thionamide antithyroid drugs like PTU or MMI. **Step 5 Colloid resorption:** Under the influence of TSH, follicular colloid–containing Tg is resorbed by the thyrocyte by pinocytosis. **Step 6 Tg proteolysis:** Thyroid hormones MIT and DIT are released from Tg under the influence of TSH. **Step 7 Deiodination:** Also stimulated by TSH at the time of secretion, deiodinase enzymes (D1,D2) are stimulated, resulting in the removal of iodide and increasing the T_3/T_4 ratio in the secreted pool. **Step 8 Secretion:** T_4, T_3, and rT_3 are released into the bloodstream. cat food preparations include at least three to five times the minimum stated requirement for iodine when fed in recommended amounts. As a result, today, documented iodine deficiency has become a rare condition in most domestic animals. During pregnancy, the recommended minimum daily requirement for iodine is increases fourfold. Areas of iodine deficiency in North America include the Great Lakes region and eastern British Columbia (Kaptein et al., 1994; Peterson and Ferguson, 1990; Zimmerman, 2013).

Ingested iodine is converted to iodide in the gastrointestinal tract and absorbed into the circulation. The dog has plasma iodide concentrations of 5 to 10 μg/dl, which are 10 to 20 times the levels in human plasma. In the thyroid gland, iodide is concentrated or "trapped" by the sodium–iodide symporter (NIS), which utilizes the sodium gradient developed by the Na^+,K^+-ATPase to move iodide through the basolateral plasma membrane of the thyroid follicular cell. This results in intracellular iodide concentrations that are 10 to 200 times that of serum. This process is stimulated by the interaction of thyrotropin (TSH) with G-protein-coupled TSH receptors on the surface of the follicular cell leading to the stimulation of cAMP (Figure 28.1). The transcription of NIS is stimulated by TSH or cyclic AMP. NIS is also upregulated directly by thyroidal mechanisms reacting to iodide insufficiency or blockade of iodide transport by compounds such as perchlorate. Other tissues, including the salivary glands, gastric mucosal cells, renal proximal tubule cells, placenta, ciliary body, choroid plexus, and mammary glands, can take up considerable amounts of radioiodide in a TSH-independent fashion.

Diagnostically, radioactive iodide or pertechnetate (TcO_4^-), which, unlike iodine, cannot be organified, can be used to assess the anion transport function (uptake) by the thyroid gland. Iodide trapping can be inhibited by other anions such as thiocyanate (SCN^-), NO_3^-, and ClO_4^-. Thiocyanate is a metabolic product of some naturally occurring compounds in plants and may result in goitrogenic (antithyroid) activity of the plant. Domestic animals may also be exposed to thiocyanate produced as a by-product of cigarette smoke in a household environment. Oral administration of perchlorate following the administration of a tracer dose of radioiodine can be used to diagnose congenital defects in the thyroidal organification of iodide (perchlorate discharge test) (Taurog, 1991; Kopp, 2013).

Thyroid Hormone Synthesis

Thyroglobulin (Tg), an iodinated glycoprotein with a molecular weight of 660,000 daltons, serves as a synthesis and storage site for thyroid hormone and its precursors in the thyroid follicle. After synthesis within the endoplasmic reticulum of the thyroid follicular cell, membrane vesicles containing noniodinated Tg fuse with the apical membrane and are released (by exocytosis) into the follicullar cell lumen where thyroglobulin is stored as colloid. Once inside the thyroid cell, iodide is transported to the follicular lumen by the protein pendrin, then oxidized by the enzyme thyroid peroxidase (TPO) to iodine (Figure 28.1). Pendrin is an apical transmembrane protein that transports sulfate, chloride, iodide, and bicarbonate (Larsen et al., 2003). Iodide is then incorporated by the heme protein enzyme thyroid peroxidase (TPO), which, in the presence of hydrogen peroxide, adds iodide onto tyrosine residues of Tg in a process called *organification,* forming monoiodotyrosine (MIT) and diiodotyrosine (DIT). TPO also forms thyroxine (T_4) by coupling two DIT molecules, and 3,5,3′-triiodothyronine (T_3) by coupling one MIT molecule with one DIT molecule (Burrow et al., 1989; Peterson and Ferguson, 1990; Taurog, 1991; Kopp, 2013). The reaction catalyzed by TPO is inhibited by the thionamide drugs propylthiouracil (PTU) and methimazole (MMI) and by high concentrations of iodide (the *Wolff–Chaikoff effect*). The intermediate product of peroxidation of iodide is either hypoiodous acid (HIO_2^-) or iodinium (I^+). The H_2O_2 required is generated by NADPH oxidase. In normal humans and rats, more than 90% of thyroidal radioiodine is organified to iodotyrosines and iodothyronines within minutes of entry into the thyroid.

When iodine intake is adequate, production of T_4 is favored. However, in iodine-deficient states and impending thyroid failure, the intrathyroidal synthesis of T_3 is preferred over that of T_4. By this autoregulation, the thyroid gland produces the most active thyroid hormone (T_3 is three to ten times more potent than T_4) while using less iodide. Conversely, chronic iodine excess may lead to excessive storage of thyroidal hormone.

The Wolff–Chaikoff effect, another intrathyroidal regulatory mechanism, is key to understanding the potential acute antithyroid effect of large amounts of ingested iodide. It is believed that, through this mechanism, the organism is protected from massive thyroid hormone release following a large dietary iodine load (Taurog, 1991; Wolff, 1989). Although the acute Wolff–Chaikoff effect is still not well understood, iodine itself has been shown to inhibit Ca^{++} (and NADPH-dependent H_2O_2) generating activity associated with NADPH oxidase, a mechanism characterized in dog, pig, and human thyroid glands. It has been proposed to be associated with autoregulation by organic iodinated compounds in the thyroid. Furthermore, this enzyme seems to be inhibited by iodinated compounds in cultured dog thyroid cells (Dugrillon, 1996; Panneels et al., 1994). In humans, the Wolff–Chaikoff effect is transient and “escape” is seen within several weeks and has been proposed to be associated with reduced iodide transport into the gland (Braverman and Ingbar, 1963).

Thyroid Hormone Secretion

Thyroid hormone secretion is initiated as the epithelial follicular cells take up thyroglobulin in colloid droplets by a process called *pinocytosis*. Simultaneously, lysosomes (containing proteases and hydrolytic enzymes) migrate from the basal region of the cell and fuse with the colloid droplets (Figure 28.1). Degradation of thyroglobulin by the lysosomal proteolytic enzymes produces both the iodotyrosines (MIT and DIT) and iodothyronines (T_4 and T_3). Little of the released MIT and DIT enters the circulation because the iodine is removed from these compounds by deiodinase enzymes (Figure 28.1). Some of this iodine is recycled internally for iodination of new tyrosine residues in thyroglobulin, but in carnivores much iodine is released to the circulation (Belshaw et al., 1974; Kaptein et al., 1994). This inefficient thyroidal reutilization of iodine may help explain the high daily iodine requirements of the dog and cat compared to humans.

Proteolysis of Tg, as described in Section Thyroid Hormone Synthesis, liberates relatively large amounts of T_4, but only small quantities of T_3, into the cytosol. 5’-deiodinase enzymes (D1 and/or D2) within the thyroid gland, however, can deiodinate T_4 to either T_3 or 3′,5′,3-T_3 (reverse T_3) and less-iodinated products. As a result, although the $T_4 : T_3$ ratio stored in the gland is 12 in the canine thyroid, the ratio of secreted products is 4. Production rates of the thyroid hormones in the dog have been estimated to be 8 μg/kg/day for T_4 and 0.8 to 1.5 μg/kg/day for T_3. In cats, T_4 production rates have been estimated to be 5.6 µg/kg/day, and 0.4 µg/kg/day for T_3. These production rates are greater than twice those for T_4 and greater than three times the rate for T_3 in humans (Kaptein et al., 1993, 1994).

Hypothalamic–Pituitary–Thyroid Extrathyroid Axis

Thyrotropin (thyroid-stimulating hormone; TSH), a glycoprotein produced in the thyrotropes of the pituitary pars distalis, has a stimulatory effect on thyroid hormone synthesis and secretion. In addition, TSH stimulates thyroid growth, probably in conjunction with actions of the insulin-like growth factors (IGF I and II). Thyrotropin has a molecular weight of about 30,000, consisting of an α subunit (identical to the α subunit of the other glycoprotein pituitary hormones luteinizing hormone, LH, and follicle-stimulating hormone, FSH), and a β subunit, which is specific to the TSH molecule (see Chapter 26). TSH binds to a specific TSH receptor on the thyroid follicular cell membrane and stimulates adenylate cyclase, the production of cyclic AMP, and the active uptake of inorganic iodide (Figure 28.1). The TSH receptors in dog, cat, and humans have been cloned and expressed. TSH also stimulates the synthesis of thyroglobulin, its release into the colloid, and its iodination by TPO (i.e., organification). As a final step in the delivery of hormone into plasma, TSH stimulates thyroglobulin resorption and proteolysis to release T_3 and T_4. The thyroidal deiodinases are also stimulated by TSH (Magner, 1990; Rapaport and Nagayama, 1992; Shupnick et al., 1989).

A detailed study of the hypothalamic–pituitary–thyroid–extrathyroid axis is only possible with the availability of a valid TSH immunoassays for each species. Availability of this assay for the dog has helped to demonstrate that most of the replacement dosages of L-thyroxine recommended are well in excess of those needed for suppression of endogenous TSH into the normal range. The currently available assays do not reliably distinguish between normal and low TSH concentrations making it more difficult to confirm an overdosage (Braverman and Utiger, 1991; Ferguson, 1984; Greenspan, 1994; Williams et al., 1996; Bruner et al., 1998). The canine TSH assay has also been used to evaluate thyroid status in the cat despite incomplete (35%) cross-reactivity for the assay (Ferguson et al., 2007). Measurement of an undetectable serum TSH concentration is a highly sensitive, but only moderately specific, test in support of the diagnosis the confirmation of hyperthyroidism, but should only be used in conjunction with measurement of total and/or free T_4 concentrations (Wakeling et al., 2011). Following surgery, radioiodine or antithyroid medication, the measurement of a normal TSH concentration with total and/or free T_4 is now recommended to evaluate treatment. There is evidence that transient hypothyroidism, associated with low total and/or free T_4 and elevated TSH, is associated with usually mild and occasionally severe renal insufficiency in cats treated for hyperthyroidism (Riensche et al., 2008; van Hoek and Daminet, 2009; Daminet et al., 2014).

The tripeptide TRH is produced in the paraventricular nucleus of the hypothalamus and transported to the pituitary pars distalis by the hypophyseal portal system in the pituitary stalk. In the pituitary gland, TRH binds to specific receptors on the thyrotrope cell and stimulates TSH secretion (Figure 28.2A). In the dog, as in other species, TRH also stimulates the secretion of prolactin. The hypothalamic hormone somatostatin acts to inhibit TSH secretion and may function as a thyrotropin inhibitory factor (Reichlin, 1986).

Negative Feedback Regulation

The negative feedback effect of thyroid hormones (in the free or unbound form) is the principal mechanism regulating TSH secretion. Tonic stimulation by TRH has a permissive role in TSH secretion. The pituitary thyrotope cell completely deiodinates T_4 (derived from the plasma) to T_3 that subsequently inhibits TSH synthesis and secretion through alteration of nuclear receptor binding, mRNA transcription, and protein synthesis. The Type II 5′-deiodinase (D2) mediates the intrapituitary conversion of T_4 to T_3, but, at the same time, T_4 inhibits D2 activity at a posttranslational level by shortening the enzymes cellular half-life through ubiquitination and subsequent proteasomal degradation (Figure 28.2B). D2 and TSH are coexpressed in thyrotrophs and hypothyroidism increases D2 expression in the thyrotroph. As a result, free T_4 (FT_4) concentration and D2-mediated T_3 production correlate negatively with expression of mRNA for TSH (Christoffolete et al., 2006).

Circulating T_4 taken up by the pituitary is the preferred source of T_3 in the pituitary, at least in the rat (Larsen et al., 1981). In human patients with hypothyroidism, thyroid replacement therapy with L-T_4 normalizes serum TSH concentrations only when the serum T_4 value is high normal to slightly high; serum T_3 concentration usually remains within normal range in these patients (Fish et al., 1987; Larsen et al., 1981).

There is also evidence that thyroid hormones may have a direct negative-feedback effect on the hypothalamus to inhibit the release of TRH (Figure 28.2A). Also, TSH and TRH may have “short-loop” and “ultrashort-loop” negative-feedback effects, respectively, upon the hypothalamus to inhibit TRH release. Although pulses of TSH secretion and an evening rise in serum TSH have been described in humans (possibly resulting from a fall in circadian circulating cortisol concentrations), studies in the dog and cat have failed to demonstrate such a circadian rhythm in circulating thyroid hormone concentrations (Fish et al., 1987; Larsen et al., 1981; Magner, 1990; Reichlin, 1986; Bruner et al., 1998; Chiamolera and

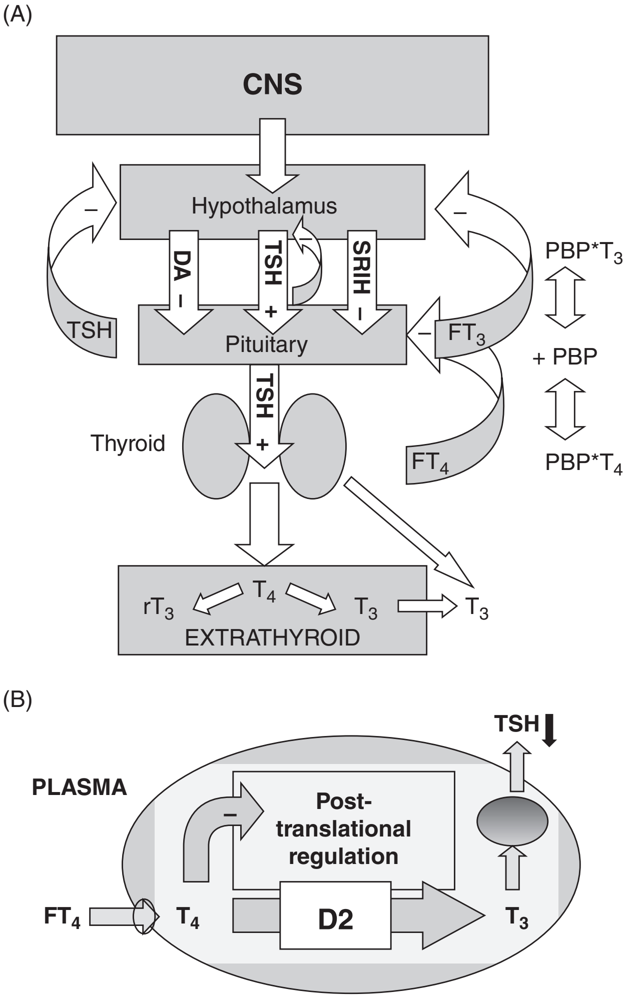

Figure 28.2 **(A)** Hypothalamic–pituitary–thyroid–extrathyroid axis. Please see text for details. TSH, thyrotropin; CNS, central nervous system; DA, dopamine; TRH, thyrotropin releasing hormone; SRIH, somatostatin; TSH, thyrotropin; FT$_3$, free T$_3$; FT$_4$, free T$_4$; PBP, plasma binding proteins; +, stimulation; –, inhibition. **(B)** Postranslational regulation of the D2 enzyme by T$_4$ in the thyrotroph cell. Free T$_4$ (FT$_4$) in the circulation is available to enter the thyrotroph, and the quantity of T$_4$ in the pituitary cell directly and rapidly inhibits the D2 enzyme, which converts T$_4$ to T$_3$. Posttranslational modification of the D2 enzyme by ubiquitination shortens the half-life of the enzyme and ultimately reduces the amount of T$_3$ produced from T$_4$. Most of the T$_3$ binding to the nuclear receptor in the thyrotroph is derived from T$_4$ deiodination. Occupancy of the TR results in down-regulation TSH mRNA and TSH secretion completing the negative feedback loop between FT$_4$ and TSH.

Wondisford, 2009). Pulsatile release of TSH has been confirmed in hypothyroid but not euthyroid dogs, but there was no overlap in values. However, TSH may not be elevated in some confirmed canine hypothyroidism cases, and TSH has been shown to rise initially and eventually fall again in chronic experimentally induced hypothyroid dogs, suggesting either pituitary resistance to lack of negative feedback by thyroid hormones or reduced synthesis and secretion of TSH over time (Kooistra et al., 2000; Diaz-Espineira et al., 2008, 2009).

Metabolism of Thyroid Hormone

The metabolically active thyroid hormones are the iodothyronines L-thyroxine (L-T$_4$) and 3,5,3′- L-triiodothyronine (L-T$_3$) (Figure 28.3). Thyroxine is the main secretory product of the normal thyroid gland. However, T$_3$, which is about three to ten times more potent than T$_4$, as well as smaller amounts of 3,3′,5′-L-triiodothyronine (reverse T$_3$), a thyromimetically inactive product, and other deiodinated metabolites, are also secreted by the thyroid gland of most mammals (Figures 28.2A and 28.3) (Belshaw et al., 1974; Ferguson, 1984; Inada et al., 1975; Kaptein et al., 1993, 1994; Laurberg, 1980).

Although all T$_4$ is secreted by the thyroid, a considerable amount (40 to 60% in the dog) of T$_3$ is derived from extrathyroidal enzymatic 5′-deiodination of T$_4$. Therefore, although it also has intrinsic metabolic activity, T$_4$ has been called a “prohormone,” and its “activation” to the more potent T$_3$ is a step regulated individually by peripheral tissues (Figures 28.3 and 28.4). The vast majority (approximately 90%) of reverse T$_3$ (rT$_3$) is derived from extrathyroidal sources in the dog (Belshaw et al., 1974; Kaptein et al., 1993, 1994; Larsen et al., 1981).

Types and Regulation of Deiodinase Enzymes

The identification of three distinct types of deiodinase enzymes has underscored the importance 1981 of the regulation of T$_3$ production in individual tissues from T$_4$. Type I 5′-D (D1) is found in most tissues, but has its highest activity in liver, kidney, muscle, and thyroid gland. This enzyme is now known to be a selenoenzyme, requiring trace quantities of selenium for optimal activity. Muscle, although it has low enzyme activity, may produce a significant amount (approximately 60% in the rat) of the body’s T$_3$ solely because of its large mass. The physiological role of D1 is the provision of *circulating* T$_3$ during conditions of euthyroidism. This enzyme is capable of “outer-ring” and “inner-ring” deiodination (ring with amino acid moiety) and can deiodinate T$_4$ with a high capacity and is sensitive to the thionamide antithyroid agent, propylthiouracil (PTU). Type II 5′-D (D2) is found in the CNS, pituitary, brown fat, and placenta, and its physiological role is provision of *intracellular* T$_3$. Its role in contributing circulating T$_3$ may increase with primary hypothyroidism. This enzyme acts upon T$_4$ and other compounds with outer-ring iodine at concentrations within the physiological range and is resistant to PTU. Type III deiodinase (D3), which is a 5-deiodinase, removes only inner-ring iodines. D3 is present in placenta, CNS, skin, and fetal brain and liver and has as its physiological role *inactivation* of T$_4$

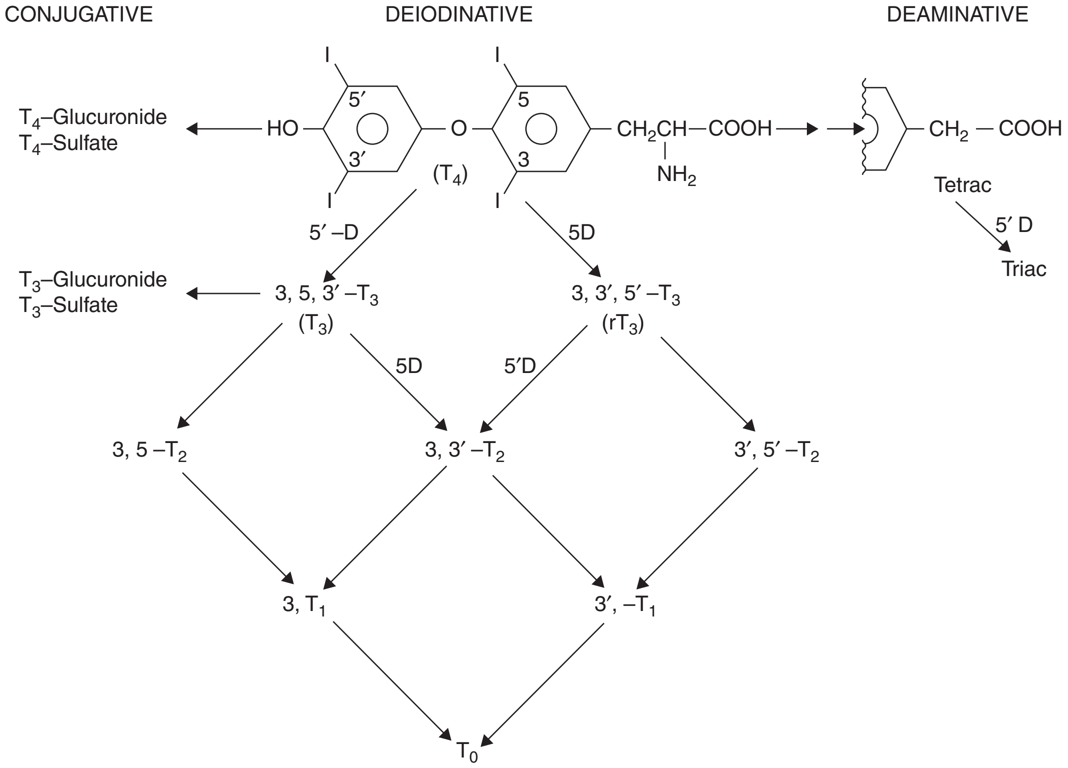

Figure 28.3 Pathways of metabolism of thyroid hormones. 5′-D, 5′-deiodinase; 5-D, 5-deiodinase. Source: Ferguson, 1984. Reproduced with permission of Elsevier.

and T_3 through inner-ring deiodination, with preference for T_3 as a substrate. Relevant to understanding the rationale for L-thyroxine therapy in hypothyroidism, hypothyroidism dramatically reduces the activity of D1 and D3 while increasing the activity of D2. Through this type of regulation, the brain may continue to obtain adequate cellular T_3 levels necessary to prevent or delay neurological dysfunction resulting from T_4 deficiency, while the liver reduces its production of T_3, thereby leading to decreased systemic metabolism (Figure 28.4). It is interesting to note that, in rodents, D1 and D3 are increased in hyperthyroidism resulting in both increased production and degradation rates for T_3. The characteristics of D1 and D2 have been examined in dogs, cats, and cattle. In cats, renal and hepatic D1 has been shown to metabolize T_4 with similar V_{max} and

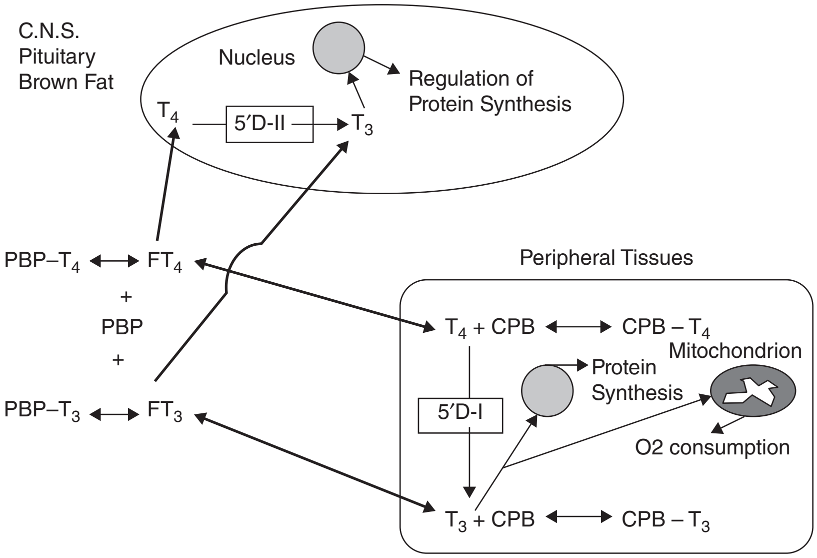

Figure 28.4 Peripheral action of thyroid hormones. T_4 and T_3, in amounts proportional to their free forms (FT_4 and FT_3) in plasma at equilibrium with plasma binding proteins (PBP), are taken up by peripheral tissues such as liver and kidney, which have the type I 5′-deiodinase enzyme (5′-D-I). T_3 from the plasma (or that derived from T_4) interacts with mitochondrial receptors to rapidly increase oxygen consumption and with nuclear receptors to initiate protein synthesis. Cytosolic binding proteins (CBP) buffer the effects of intracellular hormones and provide a relatively unsaturable hormone reservoir. In the brain, pituitary, and brown fat, another isoenzyme of the 5′-deiodinase enzyme (5′-D-II) converts T_4 to T_3. This enzyme is regulated very differently from the type I enzyme. Source: Peterson and Ferguson, 1990. Reproduced with permission of Elsevier.

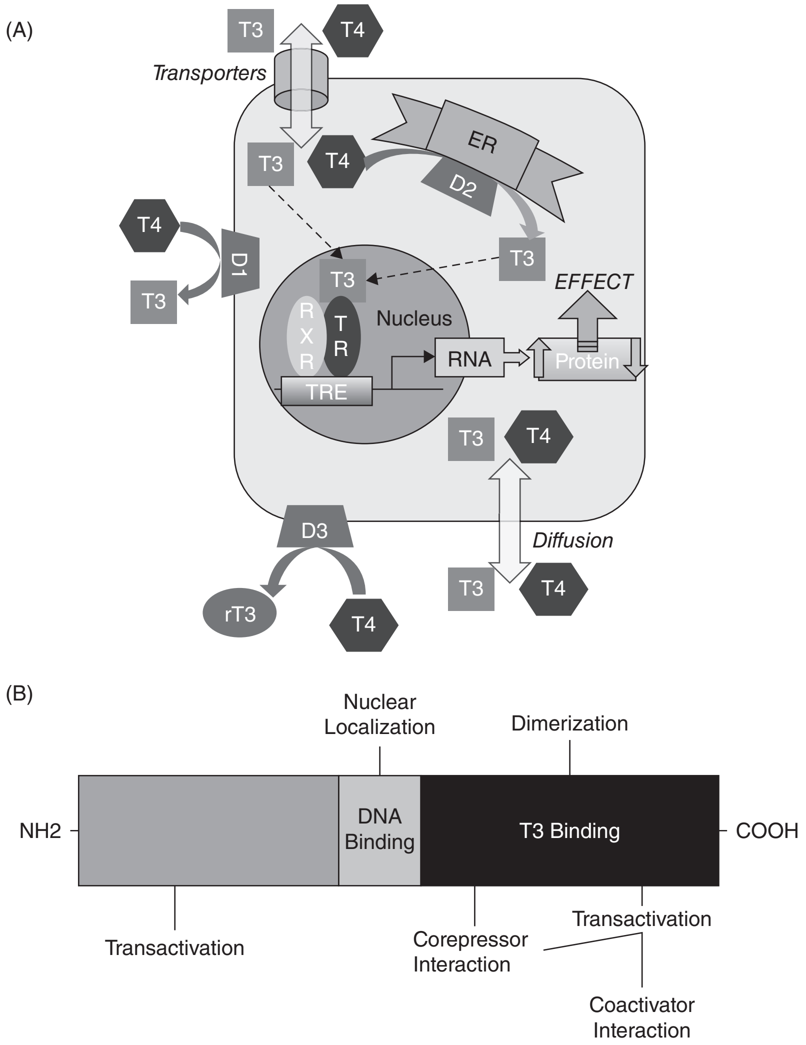

Figure 28.5 **(A)** Cellular localization of thyroid hormone transporters, deiodinases, and nuclear receptors. The D1 and D3 enzymes are plasma membrane-associated enzymes and D1 provides *circulating plasma T_3* to plasma and D3, or 5-deiodinase, leads to inactivation of T_4 to rT_3 or T_3 to 3,3′-T_2. The D2 enzyme is associated with the endoplasmic reticulum in tissues where it dominates (brain, pituitary, brown fat, etc.). Under euthyroid conditions, it provides *intracellular T_3*, but can provide a larger portion of circulating T_3 under hypothyroid conditions when D2 activity is increased. Important plasma membrane transporters for T_4 and T_3, depending upon the tissue, include monocarboxylic acid transporter 8 (MCT8) and organic acid transporter p1c1 (OATp1c1). The lipophilic hormones are also capable of diffusing through cell membranes after dissociating from thyroid binding proteins in the circulation. Once in the cytosol they also can associate with cytosolic thyroid binding protein (CTPB) until delivered to sites of action or metabolism. T_3 enters the nucleus and has high affinity for the thyroid hormone receptor (TR). TR is a heterodimer with the retinoic X receptor (RXR), which binds to the thyroid-response element (TRE), leading to a change in mRNA transcription (increase or decrease) and effects secondary to altered protein synthesis. **(B)** Functional domains of a nuclear thyroid hormone receptor. The functional domains of the thyroid hormone receptor are similar among the four active isoforms (α1, β1, β2, and β3), with the only difference being in the amino-terminal section. Coactivators and corepressors generally interact with the T_3 binding domain, which also dimerizes with the retinoic acid receptor (RXR).

Km of the rat enzyme, but the ability of the enzyme to degrade rT_3 was only about 0.2% of that of rat D1 with a Km 500-fold higher. The D1 enzyme was not identified in the cat's thyroid gland, unlike in rat, dog, and humans. These differences would imply that feline D1 does not metabolize rT_3 under physiological conditions. However, muscle D1 mRNA is stimulated by T_3 treatment of lean cats, as seen in most species. D2 has been identified in human keratinocytes as well as in dog skin. Previous studies have indicated important differences in catalytic specificity between dog and human D1, in particular with respect to the 5′-deiodination of rT_3. While D1 and D2 are found in the microsomal fraction of cells, D3 seems to be a plasma membrane protein, positioning it well to inactivate both excess T_4 and T_3 in tissues such as the placenta and brain (Figure 28.5A) (Baqui et al., 2003; Burrow et al., 1989; Ferguson, 1988; Larsen et al., 1981; Peterson and Ferguson, 1990; Foster et al., 2000; Bianco, 2002; Hoenig et al., 2008).

The process of deiodination continues until the thyroid hormone nucleus is stripped of its remaining iodine molecules thereby allowing iodine to recycle for hormone resynthesis (Figure 28.3). These further deiodinated metabolic products (other than T_3 and T_4) do not have thyromimetic activity. Evidence is accumulating that reverse T_3 may have an important role in regulating thyroid T_4 and T_3's activity in the central nervous system and 3,5-diiodothyronine (3-5-T_2) and 3-monoiodothyronine (3-T_1) may have cardiovascular effects (Ianculescu and Scanlan, 2010; Axelband et al., 2011; Dentice et al., 2013; Orozco et al., 2014). A number of nonthyroidal illnesses and drugs may affect the local tissue regulation of thyroid hormone deiodination. Other pathways of thyroid hormone metabolism include conjugation to form soluble glucuronides and sulfates for biliary or urinary excretion as well as cleavage of the ether linkage of the iodothyronine molecule (Braverman and Utiger, 1991; Burrow et al., 1989; Ferguson, 1984, 1988; Kaptein et al., 1994).

With oral administration of thyroid hormone preparations, the first-pass effect must be considered, as a large quantity of hormone can be conjugated and secreted into the bile where the hormone may either be deconjugated and reabsorbed by bacteria in the large intestine, or eliminated in the feces. The intestinal pool of thyroid hormone is known to be very large. In the dog, over 50% of the T_4 and about 30% of the T_3 produced each day are lost into the feces. In both the dog and cat, the extrathyroidal body stores of T_4 are eliminated and replaced in about 1 day, whereas stores of T_3 are lost and replaced twice daily (Kaptein et al., 1993, 1994). Such fecal wastage is responsible, in part, for the higher daily replacement doses of thyroid hormone required on a per body weight basis in dogs and cats. Despite occasional reports of massive overdoses of levothyroxine products (Hansen et al., 1992), the fecal loss pathway also accounts for the low morbidity with accidental toxicoses with thyroid hormone products in dogs. Nonetheless, demonstrating interindividual differences in sensitivity, it has been reported that a dog became thyrotoxic after coprophagia of feces from another dog in the household receiving a high dose (0.8 mg) of levothyroxine twice daily (Shadwick et al., 2013).

Plasma Hormone Binding of Thyroid Hormone

Thyroid hormones are water-insoluble lipophilic compounds. Their ability to circulate in plasma is dependent upon binding by specific binding proteins, thyroxine-binding protein (TBG) and transthyretin (TTR) or thyroxine-binding prealbumin (TBPA), as well as by albumin itself. Thyroid hormone–binding proteins provide a hormone reservoir in the plasma and "buffer" hormone delivery into tissue (Figure 28.4). TTR and possibly albumin also may serve as intermediary carriers for specific tissue uptake of the hormone by tissues (Mendel, 1989; Pardridge, 1981). The dog has a high-affinity thyroid hormone–binding protein, comparable to TBG in humans, but plasma concentrations of TBG in the dog are only 25% of those in humans. In addition to TBG, TBPA, and albumin, circulating T_4 in canine plasma appears to bind to certain plasma lipoproteins. These include a high-density lipoprotein (HDL_2), which migrates in the alpha$_1$ region on the electrophoretic pattern and a very low-density lipoprotein (VLDL), which migrates in the beta region. At normal serum T_4 concentrations in the dog, about 60% of T_4 is bound to TBG, 17% to TBPA, 12% to albumin, and 11% to the HDL_2. Thyroxine-binding globulin in the dog is not saturated until the total T_4 concentration is six times the normal serum T_4 values, while the other serum proteins are virtually unsaturable (Inada et al., 1975). The cat does not appear to have a high-affinity thyroid-binding protein (such as TBG) but has only TTR and albumin as serum thyroid hormone–binding proteins. Partly as a result of weaker serum protein binding, total T_4 concentrations are lower, the unbound or free fraction of circulating T_4 is higher, and hormone metabolism is more rapid in most domestic animals than in humans (Bigler, 1976; Kaptein et al., 1994; Larsson, 1985; Larsson et al., 1985).

Tissue Thyroid Hormone Uptake: the "Free Hormone" Hypothesis

The free hormone hypothesis, proposed by Robbins and Rall six decades ago (1960) and restated by Mendel (1989), states that it is the unbound fraction of hormone that is available to tissues and therefore proportional to the action, metabolism, and elimination of that hormone. This hypothesis has stood the clinical test of time; direct or indirect measurements of free T_4 have been a mainstay in the diagnosis of thyroid disease in human and veterinary medicine. There is also strong evidence that certain cell types actively transport or exchange thyroid hormone from the plasma into the cytosol. The presence of a plasma membrane protein specific for thyroid hormone transport (see Section Plasma Membrane Transporters and Cytosolic Binding Proteins) certainly reflects the premium the cell is willing to pay to facilitate entry and possibly concentrate thyroid hormone. However, the serum binding proteins, particularly albumin and TTR, also serve the role of distributing the hormones to specific tissues. TTR carries both thyroid hormones and retinoic acid in the circulation. Most theories of thyroid hormone exchange have assigned a passive "reservoir" role to cytosolic thyroid hormone-binding proteins (CTBP; CBP in Figure 28.4), the proteins that retain thyroid hormone in a predominantly bound state inside the cell. Little is known about the regulation of these proteins, which are often called "intracellular albumin" for their low specificity, low affinity, and high capacity. However, in renal cytosol, the affinity of CTBP may be acutely regulated by cellular redox potential, increasing when NADPH levels are high. CTBP has been shown to be identical to the protein μ-crystallin (Burrow et al., 1989; Hashizume et al., 1987; Kaptein et al., 1994; Mendel, 1989; Pardridge, 1981; Suzuki et al., 2007).

Irrespective of the mechanisms, the following observations in the clinical patient must be recognized:

1) The linear correlation between the serum free T_4 concentration, rate of hormonal degradation, and basal metabolic rate in humans.
2) The inverse correlation between the serum free T_4 concentration and the cellular distribution volume of T_4, which exists in all subjects regardless of thyroid state.
3) The positive correlation between the in vitro perfused organ free T_4 concentration and tissue T_4 uptake and T_3 production in vivo and in vitro. Most researchers agree that it is the steady-state tissue concentrations of hormone that are the driving force for thyroid hormone metabolism and action (Mendel, 1989).

In the healthy euthyroid dog or cat, about 0.1% of total concentration of serum T_4 is free (i.e., not bound to thyroid hormone-binding proteins), whereas about 1% of circulating T_3 is free (Ferguson and Peterson, 1992; Kaptein et al., 1994). The proportion of free hormone may change in response to drug administration or illness. For example, in obese cats, increased nonesterified free fatty acids compete for hormone binding, resulting in an increase in free serum thyroid hormone concentrations, and may have a similar effect to compete with cellular binding, leading to a form of thyroid hormone resistance to negative feedback manifested by an increase in total and/or free T_4 concentrations. However, it appears that thyroid status of the animal does not change, since the absolute level of the free hormone concentrations tends to soon return to within normal range or remains relatively constant (Ferguson, 1988, 1989b, 1994; Ferguson et al., 2007).

Most evidence suggests that the thyroid hormone uptake by tissues is proportional to, but not limited to, the free or unbound fraction of circulating hormone. Approximately 50 to 60% of the body's T_4 and 90 to 95% of the body's T_3 is located in the intracellular compartment (Fish et al., 1987). Certain organs, particularly the liver and kidney, can concentrate thyroid hormones and exchange hormone rapidly with the plasma. In humans, about 60% of the intracellular T_4 is in these *rapidly equilibrating* tissues (liver and kidney), whereas only 6% of the intracellular T_3 is in these tissues. About 80% of all extrathyroidal T_3 is located in the *slowly equilibrating* tissues (e.g., muscle, skin), while only 20% of intracellular T_4 is in this compartment. As a result, most of the body's T_4 is located in plasma, interstitial fluid, liver, and kidney. The majority of the body's extrathyroidal T_3 is in the cells of the muscle and skin and in a conjugated form in the intestinal tract. Kaptein et al. (1994) have used a three-pool model to describe the distribution and metabolism of thyroid hormone metabolites and iodide (Figure 28.6). Table 28.1 compares the model parameters for T_4, T_3, rT_3, and iodide in dogs, cats, and humans.

As a principle impacting the diagnosis and treatment of thyroidal diseases, the tissue-specific regulation of deiodinases and TR receptor subtypes (see Section Correlation of Clinical Effects with Cellular Actions) suggests that the determination of thyroid status really must be established on a tissue-by-tissue basis.

Metabolic Clearance Rates

The plasma half-life of T_4 in the dog has been estimated to be 8 hours (Kaptein et al., 1993, 1994), 10–16 hours (Fox and Nachreiner, 1981), and 11.6 hours (Le Traon, 2008), and 11 hours in the cat (Kaptein et al., 1994), compared to a plasma half-life of about 7 days in humans. Similarly, the plasma half-life of T_3 in the dog has been estimated to be 5–6 hours, compared to 24–36 hours in humans (Table 28.2). Studies in the normal cat indicate that the plasma half-lives of T_4 and T_3 are similar to that of the dog (Fox and Nachreiner, 1981; Kaptein et al., 1994). Despite these rates of plasma clearance, the suppressive effect on pituitary TSH secretion appears to persist at least 24 hours after a dose, suggesting that intrapituitary T_3 persists longer than the serum half-life (Ferguson, 2007; Le Traon, 2009). Therefore, as with many lipophilic nuclear receptor–mediated hormones, the plasma disappearance rates may underestimate the extent or duration of biological action.

Extrathyroidal Factors Altering Thyroid Hormone Metabolism

Effect of Illness and Malnutrition in Humans

In humans, and increasingly recognized in domestic animals, a wide range of clinical conditions, such as chronic starvation or malnutrition, surgery, diabetes mellitus, hepatic and renal disease, and chronic systemic illness, may result in decreased serum T_3 concentrations together with elevated serum rT_3 values (Araujo and

Carvalho, 2011). This "low T_3" syndrome results from inhibition of 5′-deiodinase, the enzyme necessary for conversion of T_4 to T_3 and the conversion of rT_3 to 3,3′-T_2 (Braverman and Utiger, 1991; Burrow et al., 1989; Kaptein et al., 1994; Kaptein, 1986; Daminet and Ferguson, 2003).

The reduction in the production of T_3, the most potent thyroid hormone, appears to be a beneficial adaptive mechanism by which the body serves to limit the loss of protein and perhaps blunt the metabolic rate during illness. Maintenance of serum T_3 concentrations (with triiodothyronine replacement therapy) in euthyroid fasting humans leads to excessive nitrogen excretion and blunting of the pituitary's TSH response to TRH, as if there was a state of hyperthyroidism. The body of evidence does not support the contention that lowering of serum T_3 during malnutrition and illness is associated with "tissue" hypothyroidism. Also, outside of these

regulatory mechanisms, there is, as yet, no evidence that a congenital or acquired 5′-deiodinase deficiency exists in animals or in specific tissues (Braverman and Utiger, 1991; Ferguson, 1984, 1988; Kaptein et al., 1993, 1994; Kaptein, 1986).

In acute and severe illnesses in humans, serum T_4 and T_3 concentrations may also fall, in what is called the "low T_4 state of medical illness." Impaired serum protein binding of T_4 caused by inhibitors of binding (such as free fatty acids) or a reduction in binding protein concentration results in reduced total serum T_4 concentrations and increased free fractions of T_4. In most cases, however, the absolute free T_4 concentrations remain normal. A fall in serum TSH concentrations may also contribute to the subnormal serum T_4 concentrations, especially in human patients treated with dopamine or glucocorticoids, drugs inhibiting TSH release. No studies have examined systematically the benefit or detriment of thyroid hormone therapy in domestic animals; however, studies of critically ill patients with low serum T_4 and T_3 concentrations have revealed that thyroxine therapy is not beneficial and fails to improve survival (Kaptein, 1986; Kaptein et al., 1993, 1994).

The effects of nonthyroidal illness on thyroid hormone metabolism in the dog are less well characterized than in humans. In the dog, depressed serum T_4 concentrations have been reported in various nonthyroidal illnesses such as hyperadrenocorticism (e.g., Cushing's syndrome), diabetes mellitus, hypoadrenocorticism (e.g., Addison's disease), chronic renal failure, hepatic disease, as well as a variety of other critical medical illnesses requiring intensive care (Ferguson, 1984, 1988, 1994, 2007; Ferguson and Peterson, 1992).

Effect of Drugs on Thyroid Function

This topic was reviewed by Daminet and Ferguson in 2003. A variety of drugs may impair plasma or tissue binding of the thyroid hormones or alter thyroid hormone metabolism. Drugs used in veterinary medicine that are most likely to alter circulating thyroid hormone concentrations include the glucocorticoids, anticonvulsants, quinidine, salicylates, phenylbutazone, and radiocontrast agents. The mechanisms by which these drugs exert their effect vary. Quinidine and other membrane-stabilizing drugs may inhibit 5′-deiodinase. Salicylates, furosemide, and oleic acid may directly displace thyroid hormone from plasma binding sites (Daminet and Ferguson, 2003; Ferguson, 2007; Ferguson et al., 2007). Phenylbutazone appears also to have a direct antithyroid (goitrogenic) effect in some species, having been shown to decrease total and free T_4 in the horse (Ramirez et al., 1997). In vitro, it appears to decrease serum hormone binding. Radiocontrast agents (e.g., diatrizoate, iopanoic acid, ipodate, tyropanoate, and metrizamide) may act by preventing the uptake of T_4 by tissue, by directly inhibiting 5′-deiodinase, or by releasing the iodine they contain to exert an antithyroid effect on the thyroid gland. No studies have been reported in domestic animals to evaluate the influence of these iodine-containing drugs on thyroid function tests or on subsequent radioiodine uptake (Ferguson, 1984, 1989b, 1994).

Exogenous glucocorticoids have also been shown to have a profound effect on thyroid function tests in the dog, but similar studies have had little effect on serum T_4 levels in the cat. A single high immunosuppressive dosage of glucocorticoid (2.2 mg/kg prednisone, 0.6 mg/kg dexamethasone) will lower serum T_3 but not serum T_4 concentrations in the dog (Kemppainen et al., 1983; Laurberg and Boye, 1984). Serum T_3 concentrations may be decreased because of glucocorticoid inhibition of 5′-deiodinase or simply because of a reduced availability of plasma T_4, the substrate for the enzyme. Most dogs on chronic, high-dose, daily glucocorticoid therapy will have very low or undetectable serum T_4 concentrations, as well as subnormal serum T_3 values (Ferguson and Peterson, 1992; Kaptein et al., 1992; Kemppainen et al., 1983; Moore et al., 1993; Torres et al., 1991). Based upon electron microscopic examination of thyroid tissue, it was postulated that glucocorticoids may interfere with thyroid hormone secretion by inhibiting lysosomal hydrolysis of colloid in the follicular cell (Woltz et al., 1983). *Immunosuppressive* dosages (1.1–2 mg/kg q 12 h) of prednisolone in dogs for 3 to 4 weeks significantly decreased serum total T_4 and to a lesser extent, FT_4 concentrations. These changes were observed as soon as 1 day after initiation of treatment (Torres et al., 1991; Daminet et al., 1999). Endogenous TSH was not affected by 3 weeks of an immunosuppressive dosage of prednisone, but the assay may not allow detection of a mild decrease. No changes in serum total T_4 levels were seen after a month of prednisone administration at an *antiinflammatory* dosage (0.5 mg/kg q 12 h) (Moore et al., 1993). However, a decrease in total T_3 concentrations with a supranormal T_4 increase after TSH administration was observed. Another study also showed that prednisone at an antiinflammatory dosage of 1 mg/kg/day had no effect on TSH concentration of dogs with experimental hypothyroidism, but higher dosages have not been studied. A subsequent study in T_4-supplemented hypothyroid dogs showed that prednisone at a dosage of 1 mg/kg PO q 24 h for 7 days decreased total T_4, while FT_4 was unchanged, suggesting that FT_4 may be less affected by daily prednisone administration. Subsequent antiinflammatory doses of prednisone administered every other day did not alter T_4 or TSH concentrations (O'Neill et al., 2010). In summary, glucocorticoids can markedly decrease total T_3 and T_4 concentrations and to a lesser extent FT_4 concentrations in dogs. Therefore, thyroid function test results should be interpreted carefully in any dog receiving glucocorticoids if prescribed an immunosuppressive dosage or for a period greater than 1 month (Ferguson, 1984, 1994; Moore et al., 1993; Daminet and Ferguson, 2003). In the horse, 50 g dexamethasone q 12 h topically for 10 days led to a 30–40% decrease in both T_3 and T_4 with nadir at day 2 for serum T_3 concentration and day 6 for serum T_4 concentration. Neither hormone concentration had recovered by 11 days after discontinuation of therapy (Abraham et al., 2011).

Other drugs have been well documented to alter thyroid hormone metabolism or serum or tissue binding of the thyroid hormones in the dog. The anticonvulsants diphenylhydantoin and phenobarbital, which are mixed function oxidase inducers, consistently decrease serum T_4 concentrations. Phenobarbital increases the rate of clearance of T_4. Increased hepatic deiodination of thyroid hormones, biliary clearance, and fecal excretion result in decreased concentrations of circulating thyroid hormones. The *short-term* administration (3 weeks) of phenobarbital to dogs did not affect total or free T_4 nor TSH serum concentrations in beagle dogs. However, several studies have looked at the *long-term* effects of phenobarbital administration. Total and free T_4 can be decreased to a range consistent with hypothyroidism. Endogenous TSH concentrations can remain within reference range or be slightly increased. Serum phenobarbital concentrations did correlate with the decrease in total and free T_4 concentrations in one study, but not in another. The reduction of free T_4 concentration particularly supports the idea that phenobarbital influences the steady-state clearance of T_4. Difficulty of interpretation of drug effects is compounded by the observation in dogs that seizure activity reduces serum total T_4 concentrations in proportion to the frequency of seizure episodes (von Klopmann et al., 2006). In one study, thyroid function normalized 1 to 4 weeks after discontinuation of phenobarbital. It is therefore recommended, when this is an option clinically, to evaluate thyroid function at least 4–6 weeks after discontinuation of phenobarbital (Kantrowitz et al., 1999; Gaskill et al., 1999; Müller et al., 2000; Gieger et al., 2000; Daminet et al., 1999; McClain et al., 1989; Curran and DeGroot, 1991; Johnson et al., 1993; Barter and Klaassen, 1994; Theodoropoulos and Zolman, 1989; Liu et al., 1995; DeSandro et al., 1991; Attia and Aref, 1991).

The antiepileptic potassium bromide is a halide chemically related to iodide and could potentially interact with iodine in the thyroid gland. In rats, bromide produces a relative iodine deficiency, thereby interfering with iodine uptake, iodine transport, and iodination of tyrosine and tyrosyl residues on thyroglobulin. In one study of epileptic dogs and another of healthy dogs receiving KBr at therapeutic dosages up to 6 months, no abnormal thyroid function test results were seen (Kantrowitz et al., 1999, Paull et al., 2000).

A study evaluated the effect of a standard dosage of trimethoprim/ sulfamethoxazole on thyroid function tests in dogs with pyoderma and normal baseline serum thyroxine concentrations. The average serum T_4, but not T_3, concentration fell significantly during the treatment period of 6 weeks. The TSH response also fell in several dogs and radionuclide imaging suggested that the preparation (likely the sulfa component) interfered with iodine metabolism by the thyroid gland. The thyroid carcinogenic potential of sulfonamides, which has resulted in restriction of some forms in food animals, is likely due to its goitrogenic potential, chronic elevation of serum TSH, and subsequent stimulation of thyroid growth (Hall et al., 1993). Sulfonamides are known goitrogens in domestic species because they can markedly interfere with thyroid hormone synthesis through reversible inhibition of TPO activity and reduction of serum concentrations of thyroid hormones. With reduced negative feedback, there is an increase in pituitary secretion of TSH, which induces proliferative changes in the thyroid gland. Long-term administration of sulfonamides and prolonged stimulation of the thyroid gland by TSH have been associated with thyroid neoplasia in rats. There is considerable interspecies variation with respect to TPO inhibition by sulfonamides. For example, only mild effects of sulfonamides are observed on human thyroid function. Several prospective studies have evaluated the effects of sulfonamide administration on canine thyroid function. Trimethoprim-sulfadiazine administered at a dosage of 15 mg/kg q 12 h to healthy dogs for 4 weeks had no effect on serum total T_4 or T_3 or free T_4 concentrations or upon the results of TSH stimulation tests. When trimethoprim-sulfadimethoxazole was administered to dogs with pyoderma for 6 weeks at a higher dosage of 30 mg/kg q 12 h, serum total T_4 and T_3, and FT_4 concentrations decreased. Half of the dogs in this experiment had total thyroxine (TT_4) levels below the reference range at the end of the treatment, which could easily have resulted in the inappropriate diagnosis of primary thyroid failure. In another study, the same dosage of trimethoprim-sulfadimethoxazole was given to healthy dogs for 6 weeks, and thyroid hormones were markedly decreased and endogenous TSH increased as soon as 7 days after initiation of the treatment. Thyroid imaging showed increased uptake of pertechnetate, and thyroid gland biopsies revealed hyperplasia of thyroid follicles and absence of colloid production. These findings further support the concept that sulfonamides act as goitrogens, resulting in primary hypothyroidism with secondary changes associated with the proliferative effects of TSH. The effects of sulfonamides on thyroid function are species specific, and dosage and duration dependent. Normalization of thyroid function test results in dogs after cessation of sulfonamide administration can take up to 8 or 12 weeks. Sulfa drugs can lead to clinical hypothyroidism and even goiter in some dogs (Cohen et al., 1980, 1981; Lagler et al., 1976; Panciera and Post, 1992; Post et al., 1993; Hall et al., 1993; Campbell et al., 1996; Gookin et al., 1999; Taeymans and O'Marra, 2009).

Many nonsteroidal antiinflammatory drugs (NSAIDs) have been shown to alter thyroid function tests in humans, since circulating thyroid hormones are highly protein bound, and various NSAIDs can displace thyroid hormones from serum protein-binding sites. Short-term administration of therapeutic dosages of salicylates leads to a transient increase in unbound hormone levels and suppression of TSH concentrations. After long-term treatment with salicylates, a new steady-state is reached, reflecting an increased T_4 turnover rate, and serum total T_4 concentrations have been reported to be reduced 20–40%. Free T_4 concentrations can be unchanged or decreased, and TSH concentrations return to the reference range within a few weeks of treatment. However, a 60-day double-blind study of osteoarthritic euthyroid dogs given placebo, meloxicam, carprofen, or chondroitin sulfate/glucosamine identified no drug-associated changes in serum total and free T_4 concentrations or TSH (Sauve et al., 2003).

Mechanisms of Thyroid Hormone Action

Correlation of Clinical Effects with Cellular Actions

Thyroid hormone (T_4 and/or T_3) acts on many different cellular processes via specific ligand–receptor interactions with the nucleus, the mitochondria, and the plasma membrane (Figure 28.4). The effects of thyroid hormone are seen in most tissues throughout the body. Although both L-T_4 and L-T_3 have intrinsic metabolic activity, L-T_3 is three to ten times more potent in binding to the nuclear receptors and similarly more potent in stimulating oxygen consumption (Table 28.3). Except for the deaminated form of T_4 and T_3 (tetraiodothyroacetic acid (Tetrac) and triiodothyroacetic acid (Triac), respectively),x most thyroid hormone metabolites have little thyromimetic activity. Reverse T_3 (3,3′,5′-T_3) has recently been linked to some potential developmental effects in the central nervous system.

The effects of thyroid hormone can generally be divided into those that are rapid and evident within minutes to hours of administration, such as stimulation of amino acid transport and mitochondrial oxygen

Table 28.3 Relative nuclear binding affinity of thyroid hormone analogs to T_3 . Source: Oppenheimer, 1983. Reproduced with permission of Elsevier.

	Relative binding affinity ($T_3 = 1$)	
Analog	In vitro	In vivo
L-T_3	1.0	1.0

Diiodotyrosine	0	0

cons1981umption, and those that require protein synthesis and a longer period of time (usually no sooner than 6 hours) to be manifested. Of course, the clinical manifestations may require weeks to months to clearly appreciate. About one-half of the increment in oxygen consumption produced by thyroid hormone has been related to activation of the plasma membrane-bound Na^+,K^+-ATPase, which, at least in the kidney and liver, is secondary to increases in passive K^+ fluxes caused directly and primarily by thyroid hormone via as yet undetermined mechanisms. These changes have been linked directly to the calorigenic effect of thyroid hormone. The rapid hormone effects can be observed clinically in the hypothyroid patient starting on thyroid replacement therapy by signs such as increased physical and mental activity (Braverman and Utiger, 1991; Burrow et al., 1989; Greenspan, 1994).

Chronic effects of thyroid hormone invariably are related to the cellular actions of the hormone requiring interaction with nuclear thyroid hormone receptors (TRs) followed by an increase in protein synthesis (Brent, 2012). Clinically, these are effects such as growth, differentiation, proliferation, and maturation. A common clinical presentation of thyroid insufficiency is bilateral symmetrical alopecia, the result of diminished turnover of shafts of hair within the hair follicle, resulting in greater amounts of telogen hairs. Such changes are slow in onset and, upon treatment, slow to resolve.

Plasma Membrane Transporters and Cytosolic Binding Proteins

The details of the following processes will vary depending upon the specific cell type. Free thyroid hormone (TH), translocated by passive diffusion or specific plasma membrane transporters (monocarboxylate transporter 9 (MCT-8) or organic acid transporter p1c1 (OATp1c1), depending upon the species) (Heuer and Visser, 2009) enters into the cell and binds to cytosolic thyroid binding protein (CTBP, now known as μ-crystallin) to maintain intracellular solubility and buffering, acting as a form of intracellular hormone storage. There is evidence that the affinity of μ-crystallin for TH may be increased by NADPH, resulting in another possible mechanism for an impact on cellular action. Cytosolic TH presumably exchanges with specific nuclear thyroid hormone receptors (Figure 28.5A). MCT-8 inhibitors are in development (Braun et al., 2012). It has been hypothesized that the movement of thyroid hormone from the circulation to the cerebrospinal fluid (CSF) involves entry into the choroid plexus epithelial cells via basolateral membrane TH transporters, where it binds to transthyretin (TTR) synthesized by these cells, and then moves out with TTR into the CSF or via brush border TH membrane transporters (Richardson et al., 2015).

Nuclear Thyroid Hormone Receptors

Most, but not all, of the cellular actions of thyroid hormone can be linked to binding to nuclear receptors. Thyroid hormones act by binding to a specific nuclear thyroid hormone receptor (TR), which is a heterodimer with the retinoid X receptor (RXR). TRs are members of a family of nuclear receptors similar to the v-erb A receptor, which is a receptor for the avian erythroblastosis virus, including the glucocorticoid, mineralocorticoid, estrogen, progestin, vitamin D_3, and retinoic acid receptors. There are three major functional domains of this receptor, one binding DNA, one binding the ligand, and two major transcriptional activation domains (Figure 28.5B). T_3 has a higher binding affinity for TRs than does T_4, leading to its function as the most potent thyroid hormone analogue.

The presence of multiple forms of the thyroid hormone receptor, with tissue and development stage-dependent differences in their expression, leads to an extraordinary level of complexity in the physiological effects of thyroid hormone. There are two TR genes (TRα and TRβ). Alternatively spliced gene products from each of these genes produce active (TRα-1 and TRs β1, β2, and β3) and inactive (α-2 and α-3) gene products, which are expressed in a tissue-specific manner. TRβ-2 is the subtype of the receptor in the cochlea, hypothalamus, and pituitary gland; it mediates negative feedback and is down-regulated by T_3. TRβ-1 is expressed in all tissues, with the highest levels in kidney, liver, brain, and heart. TRα-1 mRNA is expressed most highly in the brain, with lower levels in skeletal muscle, heart, and lungs. TRβ-3 mRNA is not very abundant but is found in highest levels in the liver, kidneys, and lungs. TRα-2 is found only in the heart, and in human, dog, and guinea pig, but not rodents. While not binding T_3, TRα-2 does bind the thyroid-response element (TRE) and may antagonize TRα-1's action. In addition, there are truncated proteins, with unclear physiological roles, which do not bind either T_3 or the TRE (Blange et al., 1997; Larsen et al., 2003; Bernal and Morte, 2013).

For a function directly regulated by a TR, the binding affinity of thyroid analogues directly predicts the biological activity of that analogue (Table 28.3). The binding of T_3 to the TR-TRE complex leads to stimulation or inhibition of the mRNA and protein synthesis (Figure 28.5A,B). Upon binding TH, a conformational change in the TR results in dissociation of repressors of transcription, which are replaced by coactivators, including those stimulating DNA acetylation or histone acetyltransferase activity. The latter enzyme causes dissociation of thyroid hormone–regulated genes, which then bind the transcriptional initiation complex. The action of T_3 is terminated by its dissociation from the receptor or by ubiquitination and proteasomal degradation of the hormone-bound complex.

L-T_4 is the preferred choice of thyroid hormone for therapy of hypothyroidism; although T_3 activates cellular thyroid hormone–dependent genes with highest potency, T_4 negatively regulates its own activation to T_3 by posttranslationally down-regulating D2 in the pituitary and other tissues, reducing TSH, and therefore, indirectly as well as directly, inactivating D1 (Larsen et al., 2003). Topological studies suggest that D1 is a plasma membrane protein with its catalytic site on the cytosolic surface, therefore facilitating access of the enzyme to circulating rT_3 and T_4 as well as the entry of produced T_3 into the plasma. D2 is localized to endoplasmic reticulum. These subcellular distribution patterns of the 5′-deiodinases may explain why T_3 produced by D2 is most likely to impact nuclear receptor occupancy and T_3 produced by D1 is most likely to be released to the circulation (Bianco et al., 2002; Larsen et al., 2003; Bianco and McAninch, 2013) (Figure 28.5A).

Extranuclear Actions of Thyroid Hormone

Some of the actions of thyroid hormone occur in the absence of new protein synthesis. Nongenomic actions, which include stimulation of cardiac plasma membrane Na^+ channel, the inward-rectifying and voltage-activated K^+ channels, Na^+/H^+ exchange, and the calcium pump (Ca^{2+}-ATPase), have been shown in intact cells and isolated plasma membranes. Actions on channels or pumps may contribute to setting of basal activity of these transport functions, perhaps by influencing protein kinases that modulate channel activity. Some of these nongenomic effects are now attributed to binding to αvβ3 integrin plasma membrane receptors. By interaction with these receptors, T_4 or T_3 can activate ERK1 or ERK2, which then serine phosphorylate TRb1, ERa, STAT1a, and p53 nuclear receptors that lead to mRNA synthesis for proliferative and proangiogenic proteins like basic fibroblast growth factor (bFGF) and epidermal growth factor (EGF). The integrin receptor also cross-talks with the FGF and EGF receptors. The thyroid hormone deamination product tetraiodothyroacetic acid (Tetrac) has been shown to block both the integrin and FGF receptors, and has therefore been explored as an anticancer agent (Davis et al., 2010).

A mitochondrial T_3 receptor has also been identified and has been postulated to mediate the activity of the mitochondrial adenine nucleotide translocase (ANT), indirectly stimulating oxygen consumption. The density of β-adrenergic receptors on cardiomyocytes is increased by T_3 within 2 hours even when protein synthesis is inhibited. Another nongenomic effect already described is the posttranslational inhibition by ubiquitination of the Type II 5'-deiodinase (D2) (Greenspan, 1994; Davis and Davis, 2002; Senese et al., 2014).

Physiological and Pharmacological Effects of Thyroid Hormone

Thyroid hormones, in physiological quantities, are anabolic. Working in conjunction with growth hormone and insulin, protein synthesis is stimulated and nitrogen excretion is reduced. However, in excess (i.e., hyperthyroidism), they can be catabolic, with an increase in gluconeogenesis, protein breakdown, and nitrogen wasting. Table 28.4 summarizes the multiple organ effects of thyroid hormone and the clinical manifestations of hormone deficit (hypothyroidism).

Calorigenesis and Thermoregulation

Thyroid hormones increase oxygen consumption and heat production to a large extent by stimulating uncoupling proteins (UCPs) and ANT in the mitochondria. UCPs (in particular UCP1 and UCP2) induce a H^+ leak to create inefficiency in ATP utilization resulting in heat generation (Silva, 2011). Thyroid hormone also stimulates Na^+,K^+-ATPase in all tissues except the brain, spleen, and testis. As such, thyroid hormones determine the basal (resting) metabolic rate of the animal. This results in the development of mental dullness, lethargy, and an unwillingness to exercise. The reduced basal metabolic rate results in hypothermia and the tendency for the animal to seek heat (Greco et al., 1998). Once-daily administration of 0.022 mg/kg was sufficient to normalize basal metabolic rate in dogs when measured by indirect calorimetry. Clinical signs improved in 93% of dogs with either improvement or complete resolution. This dosage was also shown to suppress TSH values to undetectable levels in most thyroidectomized dogs (Ferguson and Hoenig, 1997).

Effects on Growth and Maturation

The fetus obtains thyroid hormone from maternal sources during the first trimester of gestation in most mammals, after which the fetal thyroid function matures. Thyroid hormones are crucial for growth and development of the skeleton and central nervous system. Therefore, in addition to the well-recognized signs of adult-onset hypothyroidism, disproportionate dwarfism and impaired mental development (cretinism) are prominent signs of congenital and juvenile-onset hypothyroidism. With primary congenital hypothyroidism, enlargement of the thyroid gland (goiter) is also often observed. Puppies, kittens, and foals with this condition are behaviorally dull and less active, may have a shuffling gait, and have a poor appetite. On neurological examination, the animal is often weak, hyporeflexic, or hyperreflexic (if there is muscle tremor or spasticity), and it may lack conscious proprioception. Angular deformities have been observed in foals. Radiographic signs of underdeveloped

Table 28.4 Physiological effects of thyroid hormone. Source: Ferguson, 1989a. Reproduced with permission of Elsevier.

Site of action	Effect of hormone	Effects of deficit
Calorigenesis	Increase in BMR	Lethargy, weakness
Thermoregulation	O_2 consumption	Distal extremity hypothermia, heat-seeking
Growth and maturation	Normal CNS development	Mental retardation of cretin and dullness in adults; neuropathies
Carbohydrate metabolism	Increase in glycogenolysis and glycolysis, antiinsulin effects	Obesity despite normal or decreased appetite
Protein metabolism	Increased synthesis and degradation	Muscle weakness, poor hair coat and regrowth
Dermatological	Normal maintenance of anagen hairs, maintenance of fatty acid turnover in skin, normal keratin turnover rates	Bilateral symmetrical alopecia, hyperkeratosis, myxedema
Cardiovascular	Stimulation of myosin ATPase, stimulation of Na^+,K^+-ATPase, increased β-receptor numbers	Decreased heart rate, pulse, pressure, and cardiac output
Neuromuscular	Normal myelin production, maintenance of balance between slow-twitch and fast-twitch fibers	Polyneuropathy, muscle atrophy, weakness, stiffness, myotonia
Gastrointestinal	Maintenance of normal electrical activity of GI smooth muscle, normal segmentation	Diarrhea or constipation
Reproductive	Maintenance of normal protein synthetic rates	*Female:* anestrus, irregular cycles, galactorrhea, stillbirth *Male:* azospermia, lack of libido
Immunological	Stimulus of humoral and cell-mediated immunity	Recurrent infections (especially pyodermas)
Hematological	Bone marrow stimulation, factor VIII and VIIIAg production, normal platelet synthesis and function	Nonresponsive anemia, possible bleeding tendency
Endocrine	Normal secretion of growth hormone, gonadotropins, cortisol; inhibition of secretion of prolactin	Secondary growth hormone deficiency, galactorrhea

BMR, basal metabolic rate; CNS, central nervous system; GI, gastrointestinal.

epiphyses, shortened vertebral bodies, and delayed epiphyseal closure are common.

Effects on Lipid and Carbohydrate Metabolism

Thyroid hormone increases gluconeogenesis and glycogenolysis, contributing to its insulin antagonistic properties. Cholesterol synthesis and degradation are both increased by thyroid hormones and mediated by an increase in hepatic low density lipoprotein (LDL) receptors. Therefore, hypercholesterolemia is a common finding in hypothyroidism. Thyroid hormones stimulate lipolysis, releasing nonesterified fatty acids (NEFAs) and glycerol. Obesity may develop in some hypothyroid animals despite a normal appetite and caloric intake. In a study of lean and obese cats, T_3 administration increased thermogenesis and NEFA concentrations, as well as mRNA for adipose tissue peroxisome proliferator-activating receptor γ (PPARγ) and D1 in lean cats (Hoenig et al., 2008).

Dermatological Effects

Thyroid hormones in physiological quantities are necessary for normal hair and skin turnover. Thyroid insufficiency results in an increased percentage of telogen (inactive) hair follicles and an increase in keratin and sebum production. Dryness of the hair coat, excessive shedding, and retarded regrowth of hair are early signs of hypothyroidism in dogs. Alopecia, present in about two-thirds of affected dogs, is usually bilateral and symmetrical in distribution, and is most obvious over points of friction, such as the ventral trunk and neck, and axilla, and tail (“rattail” appearance) but also is common in the perineal area, and the dorsum of the tail and nose. The alopecia is classically nonpruritic unless secondary seborrhea or dermatitis has developed. Thickening of the skin and/or the development of myxedema (subcutaneous accumulation of glycosaminoglycans), develops in some cases. Myxedema is most prominent in the facial features, which may take on a puffy or “tragic” appearance. The type and distribution of dermal fatty acids can even be stimulated by replacement dosages of thyroid hormone in euthyroid animals. It is possible that this effect is truly a pharmacological effect of thyroid hormones and might explain the improvement in hair coat some dogs experience following thyroid hormone administration even when diagnostic tests fail to confirm hypothyroidism (Campbell and Davis, 1990).

Cardiovascular Effects

The major physiological effects of thyroid hormone on the myocardium are: (i) a direct positive inotropic effect, (ii) stimulation of myocardial hypertrophy, and (iii) increased responsiveness to adrenergic stimulation. Thyroid hormones increase the sarcolemmal Na^+,K^+-ATPase activity and favor the transcription of the α or "fast-twitch" form of the cardiac myosin ATPase improving cardiac contractility. In addition, myocardial contractility is improved by increasing the number of L-type calcium channels and enhancing sarcoplasmic reticulum calcium uptake and release. Thyroid hormones increased the number of β-adrenergic receptors in the heart, skeletal muscle, adipose tissue, and lymphocytes. In hyperthyroidism, tachycardia often results from this mechanism. Thyroid hormones also decrease α-adrenergic receptors in cardiac and vascular tissue. In hypothyroidism, the sensitivity to catecholamines in the peripheral vasculature is increased and may lead to peripheral hypothermia.

In dogs with hypothyroidism examined by an ECG, there is evidence of left ventricular dysfunction based upon cardiac echocardiography and electrocardiography. Following treatment with a replacement dosage of L-T_4 (0.5 mg/m^2 q 12 h) for 2 months, a significant decrease in shortening fraction and velocity of circumferential fiber shortening, as well as an increase in left ventricular end-systolic diameter, and prolongation of preejection period were noted when comparing measurements before and after levothyroxine supplementation. On electrocardiography, P and R wave amplitudes were significantly higher after treatment than before. Therefore, changes in cardiac function during hypothyroidism can be reversed (Panciera, 1994). Despite this, administration of the same dosage of L-T_4 to euthyroid dogs did not lead to any alteration of echocardiographic or electrocardiographic measurements (Panciera and Post, 1992). However, the majority of cats with spontaneous hyperthyroidism have echocardiographic evidence of cardiac hypertrophy and electrocardiographic abnormalities (Bond et al., 1988; Kienle et al., 1994; Fox et al., 1999).

Neuromuscular Effects

Thyroid hormones stimulate the synthesis of many proteins associated with normal nerve and muscle activity. For example, nerve Na^+,K^+-ATPase and fast forms of the myosin ATPase in muscle are stimulated by thyroid hormone. Myopathies have also been associated with hypothyroidism in domestic animals. Severe muscle weakness and delayed reflexes may be the clinical manifestation, or the signs may be vague such as stiffness, reluctance to move, and muscle wasting. Facial muscle and eyelid weakness (lip and lid droop) attributable to cranial nerve VII paralysis or paresis have been observed in dogs. Also, head tilt may be observed consistent with vestibular nerve disruption. These changes are likely due to the swelling of and around the dural sheath of the facial, vestibular, and cochlear nerves as they pass through bony foramina in the facial bones. Bilateral laryngeal paralysis has been associated with hypothyroidism in dogs as well. The pathophysiology of polyneuropathies associated with hypothyroidism is poorly understood but may be due to altered neuronal metabolism. Segmental demyelination and axonopathy has also been shown. Alternatively, compressive neurological abnormalities may be the result of tissue swelling (myxedema) surrounding the spinal cord or peripheral nerve. Clinically and electrodiagnostically, the polyneuropathy is indistinguishable from those caused by other diseases with hyporeflexia, slow nerve conduction velocities, fibrillation potentials, and positive sharp waves on electromyography. Although extremely rare, central nervous system (CNS) signs of seizures, disorientation, and circling also have been reported in hypothyroid dogs with cerebrovascular atherosclerosis caused by the hyperlipidemia associated hypothyroidism. Severe mental obtundation can be also observed in the syndromes of cretinism and myxedema coma.

Gastrointestinal Effects

Studies in hypothyroid dogs have demonstrated a decrease in the intestinal and gastric electrical and motor activity. Although hypothyroid dogs usually have normal bowel movements, constipation and diarrhea have been also observed.

Reproductive Effects

Normal thyroid hormone concentrations appear to be important for normal reproductive cycling of mammals. Hypothyroidism has been associated with a variety of reproductive disturbances in dogs and horses. In breeding bitches, persistent or sporadic anestrus, infertility, abortion, and high puppy mortality have been observed. Galactorrhea is a rare sign of hypothyroidism that develops in some intact female dogs whose mammae have been primed for lactation. Hyperprolactinemia, perhaps resulting from the excessive stimulation of prolactin-secreting pituitary cells by TRH, appears to be the cause of galactorrhea in susceptible bitches and may be at least partially responsible for the infertility associated with canine hypothyroidism. Lack of libido, testicular atrophy, hypospermia, or infertility have been suspected in the male with hypothyroidism, but studies of thyroidectomized dogs showed no changes in sperm count or motility. It is possible that there are components of autoimmune orchitis coexisting with autoimmune thyroiditis in the spontaneously developing form of hypothyroidism.

Immunological Effects

Any dog with a recurrent infection, particularly of the skin, should be evaluated for hypothyroidism. Pyoderma, which is unresponsive or only temporarily responsive to appropriate antibacterial agents, may be exacerbated by the reduced phagocytic function of white blood cells in hypothyroidism.

Hematological Effects

The increased cellular demand for oxygen stimulated by thyroid hormone leads to increased production of erythropoietin and increased red blood cell production by the bone marrow. Thyroid hormones also increase the 2,3-diphosphoglycerate content of erythrocytes, allowing increased oxygen dissociation from hemoglobin and increased availability to tissues.

A cause-and-effect relationship between canine hypothyroidism and the development of an acquired coagulation defect (von Willebrand's disease) has been postulated, but controlled studies in hypothyroid dogs have not confirmed a relationship. Similarly, in dogs with von Willebrand's disease treated with thyroid hormone, a rise in factor VIII antigen has been described even when little evidence of primary hypothyroidism exists. The mechanism of action of thyroxine in these circumstances is uncertain, but may reflect the nonspecific action of thyroid hormone on protein synthesis. Since the breed incidence of von Willebrand's disease and hypothyroidism overlap (e.g., Doberman Pinscher, Golden Retriever, Miniature Schnauzer), it is critical to rule out the coexistence of these conditions in individual dogs where hypothyroidism may unmask a subclinical bleeding tendency. Platelet number and function can be decreased in hypothyroidism.

Endocrine Effects

Thyroid hormones influence the normal secretion and metabolism of a variety of hormones and xenobiotics. Secretion of growth hormone, gonadotropins, and cortisol are stimulated by thyroid hormones and prolactin secretion is inhibited. Hypothyroidism may cause galactorrhea due to the subsequent increase in prolactin secretion in this condition (Braverman and Utiger, 1991; Burrow et al., 1989; Ferguson, 1989a, 1993; Peterson and Ferguson, 1990; Ferguson and Hoenig, 1991b; Greenspan, 1994; Panciera and Johnson, 1994, 1996; Johnson et al., 1999).

Thyroid Hormone Preparations

Thyroid hormone preparations can be classified into the following groups: (i) crude hormones prepared from animal thyroid gland; (ii) synthetic L-thyroxine (L-T_4); and (iii) synthetic L-triiodothyronine (L-T_3), and combinations of T_4 and T_3. The available products and dosage ranges are listed in Tables 28.5 and 28.6. The American Thyroid Association task force on thyroid hormone replacement has extensively reviewed the physiological principles and human clinical data regarding rationale and efficacy of thyroid hormone replacement products (Jonklaas et al., 2014). Many of these principles apply to veterinary applications as well and are reiterated here.

Crude Thyroid Products

Thyroid hormone products derived from thyroid tissue from hog, sheep, or cattle are available in the forms of desiccated thyroid (thyroglobulin). There are no good reasons to continue to use these products for replacement therapy in small animals; however, due to decreased cost, these products still have some utility in large animals. Problems with desiccated thyroid products include a highly variable content of T_4 and T_3, unphysiologically low ratios of T_4/T_3 (2 to 4), and short shelf life; these drawbacks outweigh the lower cost of these products. Standards set by the US Pharmacopoeia for control of hormone content may have improved the reproducibility of these products but are unlikely to eliminate the other disadvantages. However, a double-blind study in human patients compared desiccated thyroid to synthetic levothyroxine. Desiccated thyroid extract use led to greater weight loss, but there was no difference in psychometric testing or in any symptoms, and both products normalized hormonal concentrations. Both types of thyroid hormone were able to normalize the abnormal thyroid blood tests (Hoang et al., 2013).

Synthetic L-Thyroxine

Levothyroxine (L-T_4) is the thyroid hormone replacement compound of choice in all species. It is generally formulated and used as levothyroxine sodium for oral administration. Injectable forms are also available (for the rare indication of myxedema coma). Thyroxine is recommended for the following reasons:

1) L-T_4 is the main secretory product of the thyroid gland.
2) L-T_4 is the physiological "prohormone"; administration of L-T_4 does not bypass the cellular regulatory processes controlling the production of the more potent T_3 from T_4 (5′-deiodination).
3) In human patients with untreated hypothyroidism, serum TSH concentrations correlate inversely with serum free T_4 concentrations but to a lesser extent with serum T_3 concentrations. However, as mentioned previously, there is some evidence that there might be some clinical benefits associated with administration of a small amount of T_3 in humans,

Table 28.5 Levothyroxine products (all products are oral unless otherwise designated)

Product	Manufacturer	Starting dosage and frequency
Approved for Veterinary Use		
Thyro-Tabs Canine[a]	Lloyd	0.022 mg/kg q 24 h
Available but not FDA-approved for equine use[b]		
Thyro-L Equine Powder	Lloyd	0.01–0.1 mg/kg q 24 h or divided q 12 h; do not exceed 100 mg/horse/day
Thyroxine-L Powder	Allivet Pet Pharmaceuticals	
Thyrovet Equine Powder	Allivet Pet Pharmaceuticals	
Thyrozine Powder	Phoenix	
Approved for human use but available for veterinary use		
Levolet	Vintage (not marketed in the USA)	Note: for all products below and unapproved veterinary products on market: For dogs and cats, 0.022–0.044 mg/kg q 24 h or divided q 12 h may allow for variation in oral bioavailability; exceed only with caution 1 mg/day in dogs and 0.2 mg/day in cats
Levo-T	Alara Pharm	
Levothroid (oral and injectable)	Lloyd (distributed by Actavis)	
Levothyroxine Sodium	Genpharm	
Levothyroxine Sodium	Mylan	
Levoxyl	Jones Pharma/King	
Synthroid (oral and injectable)	AbbVie	
Tirosint	Institute Biochimique	
Unithroid	Jerome Stevens	

*[a] In January, 2016, the FDA issued letters to six manufacturers of the unapproved levothyroxine products stating “Unapproved animal drugs have not been reviewed by FDA and may not meet the agency’s strict standards for safety and effectiveness. They also may not be properly manufactured or properly labeled. FDA advises veterinarians and dog owners to avoid using unapproved levothyroxine products.” The warning letters targeted these unapproved levothyroxine products: Thyrosyn, Soloxine, Levocrine, Thyroxine L, Thyrovet, Thyromed, Thyroid Chewable Tablets, Thyrokare, Leventa. (https://www.fda.gov/animalveterinary/newsevents/cvmupdates/ucm482928.htm, January 29, 2016).
As of publication date, the only approved veterinary product for levothyroxine is Thyro-Tabs^{TM} (Lloyd, Inc.). Other products appear to have been removed temporarily or permanently from manufacture and additional distribution. Veterinarians should contact manufacturers directly for the most current status of these products. Some of these products may also still be distributed outside the USA (https://www.fda.gov/AnimalVeterinary/Products/ApprovedAnimalDrugProducts/UCM042860.pdf, accessed March, 2017).
†[b] There are no approved levothyroxine supplements for horses or cats.

Table 28.6 L-Triiodothyronine, combination levothyroxine/L-triiodothyronine and dessicated thyroid products approved by FDA for human use (oral unless otherwise designated)

Product	Manufacturer	Dosage and Frequency
L-Triiodothyronine		
Cytomel	Pfizer	Dogs: 0.004–0.006 mg/kg q 8–12 h Cats (T3 suppression test): 0.025 mg q 8 h × 7 doses
Liothyronine Sodium	Mylan	Dogs: 0.004–0.006 mg/kg q 8–12 h Cats (T3 suppression test): 0.025 mg q 8 h × 7 doses
Triostat (injectable)	JHP Pharmaceuticals, X-Gen Pharmaceuticals	Not available for dogs, cats, or horses
Levothyroxine/L-triiodothyronine		
Thyrolar (4 : 1 T4/T3 ratio)	Actavis	Based upon T4 dosage; see above
Dessicated thyroid		
Armour Thyroid	Allergan	Dosage not available for dogs and cats; 15 grains/day q 24 h for horse
Nature Thyroid	RLC Laboratories	Dosage not available for dogs and cats; 15 grains/day q 24 h for horse

and studies in rodents have long shown that normalization of TSH values with T_4 monotherapy often results in T_4 values, which are in the high normal or high range.

4) The therapeutic goal should be to normalize both tissue and serum T_4 and T_3 concentrations, and this is accomplished only in tissues with exogenous T_4 administration.
5) The central nervous system and pituitary derive a large proportion of intracellular T_3 from local 5′-deiodination of T_4 by D2. With administration of T_3, the serum T_3 concentrations must be higher than normal to normalize serum TSH (Figure 28.7).
6) In general, variability in the bioavailability of synthetic T_4 preparations is less than for the crude products.
7) L-T_4 is less expensive than other synthetic preparations.

Quality Control of Thyroid Hormone Products

In 1982, the US Pharmacopoeia adopted a new method for the assay of hormone content in thyroid hormone preparations. The old, less accurate determinations based upon iodine content were replaced by high pressure liquid chromatographic (HPLC) determination. Initially, studies of brand-name and generic L-thyroxine preparations showed that the hormonal content of some generic tablets may be as little as 30% of the amount stated on the label. The problems with variable hormone content have largely been addressed by the new standards. However, it is not safe to assume that the relative bioavailability of one thyroid hormone preparation is equivalent to another. Therefore, when starting an animal on a thyroid replacement product, it is recommended to start with a brand-name product (or proven generic product) with which broad experience has been obtained and use this product until a distinct clinical response has been seen. If no response is seen at a reasonable dose after a period of at least 4–6 weeks, and normal serum T_4 concentrations are achieved after administration, the diagnosis should be reevaluated. Except for financial reasons, the concern about mild overreplacement is minimal in most cases since the dog (as well as the cat) is very resistant to the development of thyrotoxic signs, requiring 10 to 20 times the replacement dose chronically in order to demonstrate signs. This is likely the result of the dog's and cat's capacity to efficiently clear thyroid hormone via biliary and fecal excretion (Ferguson, 1986; Kaptein et al., 1994).

Dosage Considerations for L-Thyroxine

Thyroid hormone replacement therapy is almost always indicated for the remainder of the dog's life. Therefore, careful initial diagnosis and tailoring of treatment is essential. A variety of dosage regimens for T_4 therapy have been recommended. This probably reflects the variation between animals in hormone absorption and metabolism, the variable degree of remaining endogenous hormone secretion by the failing thyroid, the possible effect of circulating anti-T_4 antibodies in a subgroup of animals, the resistance to the development of thyrotoxicosis with overdoses in the dog, and the vague and variable criteria by which clinical improvement is judged. With the advent of the canine TSH assay, objective analysis of the body's response (at least the pituitary's) to

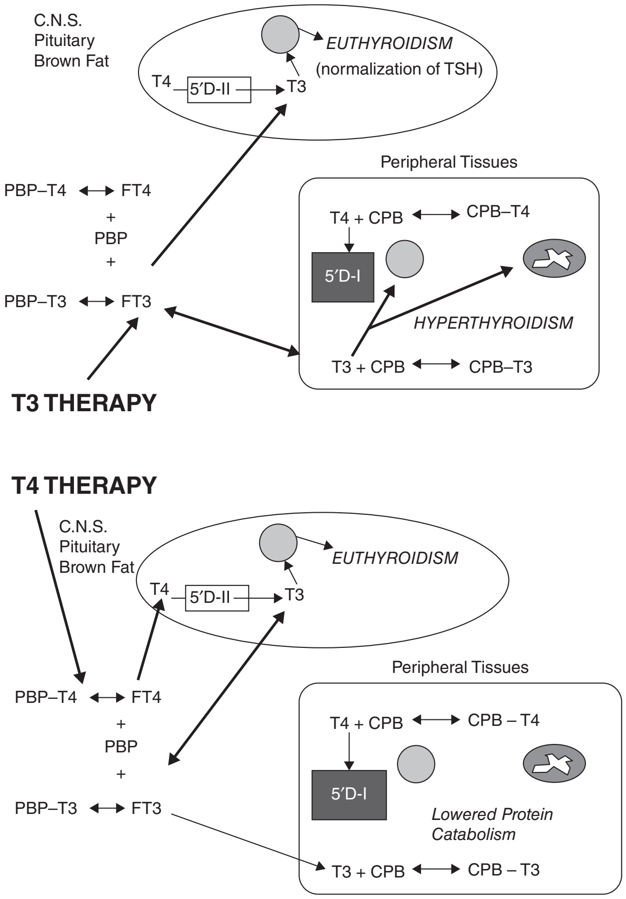

Figure 28.7 Thyroid replacement therapy of hypothyroidism with L-T_3 (*top*) or L-T_4 in supervening nonthyroidal illness. *Top*, L-T_3 therapy during nonthyroidal illness bypasses the individual tissue regulation of the 5′-deiodinase enzymes. Shown is the scenario when the amount of T_3 administered is sufficient to recreate euthyroidism in the pituitary, brown fat, or CNS. In the pituitary, TSH secretion would be reduced to normal. This amount of T_3 would be excessive for tissues such as the liver and kidney, which are trying to limit protein catabolism during illness. A state of tissue hyperthyroidism results. *Bottom,* In contrast to therapy with L-T_3, L-T_4 therapy allows individual tissues to regulate T_3 production. Therefore, the brain, pituitary, and brown fat continue to produce adequate amounts of T_3 derived from plasma T_4, but the liver, kidney, and other tissues reduce local T_3 production, allowing a lowering of protein catabolism in illness. PBP, plasma binding protein; CBP, cytosolic binding protein; FT_3, free triiodothyronine; FT_4, free thyroxine. Source: Peterson and Ferguson, 1990. Reproduced with permission of Elsevier.

exogenous hormone replacement is now possible and is routinely used in the monitoring of human patients with hypothyroidism. Using the FDA-unapproved veterinary L-thyroxine product Soloxine^{TM}, serum TSH concentration was suppressed to undetectable concentrations by 0.02 mg/kg or less of L-T_4 given only once daily (Ferguson, 2007).

In addition to the aforementioned effects of concomitant drug therapy on thyroid hormone metabolism, increased doses of T_4 appear to be necessary in hypothyroid humans during the colder months of winter. While similar studies of L-T_4 dosage have not been performed in animals, seasonal variations have been seen in dogs exposed to significant seasonal changes in light, as in racing dogs in Alaska. It is possible that an animal housed outdoors might require a higher dose of T_4 than an animal predominantly in the house, particularly during the colder months. In the dog, as in humans, basal serum concentrations of T_4 decrease with age. It has been observed in humans that older hypothyroid patients require lower doses of T_4 for adequate replacement, and are more apt to develop the adverse effects of slight thyroid hormone overdoses (Ferguson, 1986; Rosychuk, 1982).

Levothyroxine Dosages for the Dog

Based upon isotopic kinetic studies, L-thyroxine is produced and degraded at the rate of 7 μg/kg/day in dogs (Table 28.2) (Kaptein et al., 1993, 1994). In general, reported oral replacement doses for T_4 in the dog range from a total dose of 0.02 to 0.04 mg/kg daily. Based upon this indirect evidence and unpublished studies by the author of the oral bioavailability of common brands of levothyroxine, the fraction of oral absorption of L-T_4 products may range from 10 to 50%, averaging 35% (Ferguson and Hoenig, 1997), in part explaining the variation of necessary oral dosage to attain clinical euthyroidism. Therefore, if the daily production rate of T_4 is 7 μg/kg/day, and average bioavailability is 35%, a total daily dosage of 20 μg/kg or 0.02 mg/kg is predicted. In a study of a commercial liquid levothyroxine product, the dosage of 20 μg/kg once daily resolved clinical signs in 91% of dogs after 4 weeks of therapy. Following clinical signs, and total T_4 and TSH concentrations, once-daily maintenance dosages at steady-state were 20 μg L-T_4/kg BW for 79% of the dogs, 30 μg/kg for 15%, and 10-15 μg/kg in 6% (Le Traon, 2009). In addition, serum TSH concentrations were suppressed for at least 24 hours (Le Traon, 2009). A later study of chronic therapy demonstrated that only one out of 10 hypothyroid dogs required twice-daily oral replacement dosing to maintain clinical response (van Dijl et al., 2014).

Pharmacokinetic studies of a levothyroxine solution product in healthy dogs demonstrated 22% bioavailabiity with a maximum concentration at 3 hours postdosing, and half-life of 11.6 hours. Food intake concomitant with L-T_4 oral administration delayed L-T_4 absorption and decreased its rate and extent by about 45%. The relative bioavailability of L-T_4 following administration of a tablet formulation was about 50% of that of the L-T_4 solution. The pharmacokinetic properties of an oral L-T_4 solution support the use of a dose rate of 20 μg/kg once daily as a starting dose for replacement therapy in dogs with hypothyroidism (Le Traon et al., 2008). Although bioavailability of this same product was reduced 45% by concomitant feeding (Le Traon et al., 2008), the composition of the food (protein, fiber, etc.) does not seem to impact the resulting bioavailability (Iemura et al., 2013).

It has also been proposed that the dosage might be calculated according to body surface area (BSA) (0.5 mg/m^2) with the reasoning that it is proportional to the metabolic rate. When the L-T_4 dosage is determined on a body weight basis, large breed dogs have a greater tendency to develop thyrotoxicosis, or at least elevated serum T_4 concentrations. For example, according to body surface area, a 5-kg (0.29 m^2 BSA) dog would start on a dose of 0.15 mg L-T_4 daily, or 0.03 mg/kg. A 50-kg dog (1.36 m^2 BSA) would start on 0.70 mg/day, or less than half the dose according to body weight, 0.014 mg/kg. There are no published experimental studies, however, to confirm the validity of this dosing method. It is rarely necessary to exceed 1 mg of levothyroxine per day in dogs, but some experts place the upper dosage at 1.6 mg per day (Ferguson, 1986; Ferguson and Hoenig, 1991b; Ferguson et al., 1992; Rosychuk, 1982).

As thyroid replacement therapy is initiated, a common practice is to divide the total daily dosage into two separate doses given at 12-hour intervals. Because of the significant intracellular capacity for storage of T_4, particularly in rapidly exchanging pools like liver and kidney, the initial oral doses of thyroid hormone may be substantially distributed into tissue stores, the hormone stores of the liver and kidney are repleted to euthyroid levels, and then can serve to "buffer" serum concentrations when the circulating hormone "store" bound to binding proteins are depleted. As previously outlined, hypothyroidism reduces the deiodinative and conjugative rate of thyroid hormone metabolism. Division of the daily dose reduces the metabolic effect of a bolus of thyroid hormone on hypothyroid tissues and decreases the "one-pass" effect (i.e., hepatic metabolism and excretion of a portion of a bolus dose of hormone before ever reaching the systemic circulation). In the rat, the largest compartment for thyroid hormone has been shown to be the gastrointestinal tract. The clinical result is that many hypothyroid animals can be maintained on once-daily T_4 therapy despite the fact that the serum half-life is much shorter. In humans, it seems that clinical improvement and suppression of serum TSH can be maintained by any replacement regimen that, over the course of a day, leads to a normal average serum concentration without leading to the acute toxic effects of thyroid hormone. Although the serum T_4 concentration might be high at one time of the day and low at another, the tissue response "integrates" the serum concentration throughout the day, thereby reflecting the average concentration. Once-daily administration also leads to greater compliance by owners. In an animal that has responded to twice-daily therapy, the reappearance of clinical signs of hypothyroidism on a once-daily regimen should be a signal to return to the successful twice-daily regimen. Because the metabolism of thyroid hormone changes with correction of hypothyroidism, dosage regimes should be reassessed by clinical and laboratory criteria after at least 4 weeks of initial therapy.

Levothyroxine Dosages for the Cat

As in the dog, the recommended treatment for feline hypothyroidism is daily administration of L-thyroxine, using an initial dose of 0.05–0.1 mg twice daily (Peterson, 2013). This dosage should subsequently be adjusted on the basis of the cat's clinical response and post-pill serum T_4 evaluation (as described in Section Monitoring Therapy). Complete resolution of clinical signs can usually be expected in cats with adult-onset iatrogenic hypothyroidism. However, the mental dullness and dwarfism that develops in kittens with hypothyroidism usually persist because of delayed period of time from onset to diagnosis in these cats (Peterson and Ferguson, 1990; Rosychuk, 1982). The use of levothyroxine therapy following surgery or radioiodide therapy to treat resulting hypothyroidism has been shown to reduce the severity of post-treatment azotemia (Williams et al., 2014).

Levothyroxine Dosages for the Horse

There is little published information establishing therapeutic criteria for levothyroxine dosing in the horse. The oral L-T_4 dosage required clinically appears to depend largely on the form of hormone (crude versus synthetic) used for replacement therapy. The recommended starting dosage of levothyroxine has been 20 μg/kg/day orally (Frank et al., 2002). Higher dosages have been tolerated for short periods, but likely because it was given with grain, as fiber or bran may decrease oral absorption in humans (Breuhaus, 2002). Iodinated casein contains approximately 1% T_4 and is given at 5 to 15 g/horse/day orally (Lowe et al., 1974).

Synthetic L-Triiodothyronine

Although T_3 is the active intracellular hormone, there are few valid reasons to use this product for replacement therapy and some good reasons not to use it. Triiodothyronine therapy is not physiological as it bypasses the final cellular regulatory step of 5′-deiodination of T_4 (Figure 28.7). Thyroxine does have intrinsic thyromimetic activity. Its role is particularly important in the central nervous system and pituitary, tissues in which normalization of the intracellular T_3 concentration depends upon the normalization of both serum T_4 and T_3. Treatment with T_3 alone may provide amounts sufficient for organs like the liver, kidney, and heart, which derive a high proportion of T_3 from plasma. However, the brain and pituitary, which derive a majority of their T_3 from T_4 intracellularly, may then be deficient in thyroid hormone. Conversely, T_3 therapy adequate for the brain and pituitary may be excessive for the liver, kidney, and heart (Figure 28.7, top).

At present, it cannot be recommended that T_3 therapy be instituted in the "low T_3 syndrome" associated with nonthyroidal illness. Because of its higher oral bioavailability, it may be used to improve the clinical response in a dog with demonstrated or suspected poor T_4 absorption in which posttherapy serum T_4 and T_3 concentrations remain low despite increases in the oral daily T_4 dose. Triiodothyronine therapy may be indicated when thyroid replacement is necessary with the simultaneous administration of drugs, such as glucocorticoids, which inhibit the conversion of T_4 to T_3.

Anecdotal reports suggest that a small fraction of hypothyroid dogs convert T_4 to T_3 poorly in the absence of obvious nonthyroidal illness, and therefore do not respond to L-T_4 therapy. Triiodothyronine therapy has been recommended in these cases as an adjunct to T_4 or as sole therapy. The most likely cause of apparently low serum T_3 concentrations and normal or high T_4 concentrations following T_4 therapy is the presence of anti-T_3 antibodies that, in certain T_3 radioimmunoassays, will result an extremely low reading for the T_3 concentration. This observation is an in vitro artifact that has no relevance to the choice of replacement therapy products. Because the binding capacity of antithyroid hormone antibodies is easily overcome in most cases, it is recommended that usual dosages of L-T_4 be administered and the dose increased (if needed) until a clinical response is seen. The posttreatment serum T_3 concentration should be ignored in these dogs with T_3 autoantibodies (Ferguson, 1986; Rosychuk, 1982).

Combination T_4/T_3 Therapy

A study in humans compared the administration of solely T_4, with replacing 50 μg of the normal T_4 dose with 12.5 μg of T_3. Using neuropsychological methods for evaluation, the T_3-treated individuals showed improved cognitive performance (Bunevicius et al., 1999). This approach is controversial because other studies have not confirmed the finding. Similar studies have not been conducted in domestic animals.

Triiodothyronine Suppression Test in the Cat

As part of a workup for hyperthyroidism in cats, the administration of L-T_3 is utilized to evaluate the autonomy of thyroid secretion from the influence of pituitary TSH. L-triiodothyronine is administered at a dose of 25 µg every 8 hours for 2 days, giving a seventh dose on the morning of the third day. A blood sample for serum T_4 measurement is taken before T_3 administration and again at 4 hours after the last dose. Presumably mediated via a fall in pituitary TSH, serum T_4 is depressed by at least 50% in normal cats, whereas little suppression is seen in cats with hyperthyroidism because TSH is already depressed. The advantages of this test are that the doses of T_3 can be given at home on an outpatient basis with an office visit 4 hours after the last dose (Graves and Peterson, 1994; Peterson and Ferguson, 1990). The disadvantage is that there may be less than full compliance with successful administration of the seven doses of L-T_3 by the owner.

Effects of Thyroid Hormone Overdose (Iatrogenic Thyrotoxicosis)

Except for financial reasons, the concern about mild overreplacement is minimal in most cases as the dog is very resistant to the development of thyrotoxic signs. This resistance to iatrogenic thyrotoxicosis is the result of the dog's capacity to efficiently clear thyroid hormone via biliary and fecal excretion. Animals on replacement therapy, particularly with a T_3-containing product, can develop signs of thyrotoxicosis, particularly in large breed dogs dosed on a body weight basis; however, the incidence at recommended doses is rare. Animals should be monitored for signs suggesting an overdose including polyuria, polydipsia, nervousness, weight loss, increase in appetite, panting, and fever. Diagnosis is confirmed by elevated serum T_4 and/or T_3 concentrations and the amelioration of signs by temporary discontinuation of therapy. Following accidental ingestion of massive amounts of levothyroxine, dogs should be treated with activated charcoal within several hours of ingestion, possibly managed with β-adrenergic blockers if tachycardic, and heart rate and body temperature should be carefully monitored. Clinical experience has generally shown that dogs survive intoxication with few side effects despite considerable elevations in serum T_4 and T_3 concentrations.

Therapeutic Trial for Diagnosis of Hypothyroidism

Thyroid replacement therapy, without confirmatory laboratory evidence of hypothyroidism, has been suggested as a valid diagnostic step in a dog suspected to be hypothyroid. Although the major factor cited in defense of this practice is the cost of the diagnostic testing for the owner, it should be emphasized to an owner that replacement therapy is generally necessary for the remainder of the animal's life. Therefore, an incorrect diagnosis (and unnecessary long-term thyroid hormone treatment) can also be quite expensive. In one study of normal dogs given L-T_4 at the dosage of 0.5 mg/m^2 twice daily, the mean serum T_4 response to exogenous TSH had suppressed to 56% and 46% of the pretreatment value when retested at 4 and 8 weeks on treatment, respectively. Four weeks after cessation of L-T_4 therapy, the serum T_4 response to TSH was still slightly suppressed, indicative of residual thyroid atrophy (Panciera et al., 1990). Therefore, if TSH stimulation testing is used to confirm the diagnosis of hypothyroidism in a dog that has recently been receiving thyroid hormone, TSH testing should not be performed for at least 4 weeks following discontinuation of thyroid hormone replacement therapy.

Monitoring Therapy

The most important indicator of the success of thyroid replacement therapy is the progress made toward ameliorating clinical signs. Before therapy is begun, the clinician and owner should have a clear idea of the goals of therapy and the time frame in which these goals can reasonably be achieved. The reversal of changes in haircoat and body weight should be assessed no sooner than after 2 months of therapy. In cases in which clinical improvement is marginal or signs of thyrotoxicosis are seen, the clinical observations can be supported by therapeutic monitoring of serum thyroid hormone concentrations (post-pill testing). Clearly, the documentation of distinctly elevated serum T_4 concentrations following T_4 administration and elevated serum T_3 concentrations following T_3 administration, concomitant with signs of thyrotoxicosis, confirm an overdose. The interpretation of post-pill serum thyroid hormone concentrations in cases of suspected underdosing can be more complicated because the timing of sampling may be critical to the proper interpretation (Nachreiner et al., 1993). Ideally, therapeutic monitoring should not be attempted until steady-state conditions are reached, minimally 1 week after the initiation of therapy from a pharmacokinetic standpoint, but probably 1 month after initiation of therapy from a pharmacodynamic and clinical standpoint. With once-daily T_4 administration, the peak serum concentrations of T_4 generally should be in the high-normal to slightly high range 4–8 hours after dosing and should be low-normal to normal 24 hours after dosing. Given the dog's resistance to signs of thyrotoxicosis, it may be reasonable and adequate to check the serum T_4 concentration 24 hours after the previous day's dose. This is the method of choice of the author. In this situation, serum T_4 concentrations should still be in the normal range. Some endocrinologists prefer to measure "peak" T_4

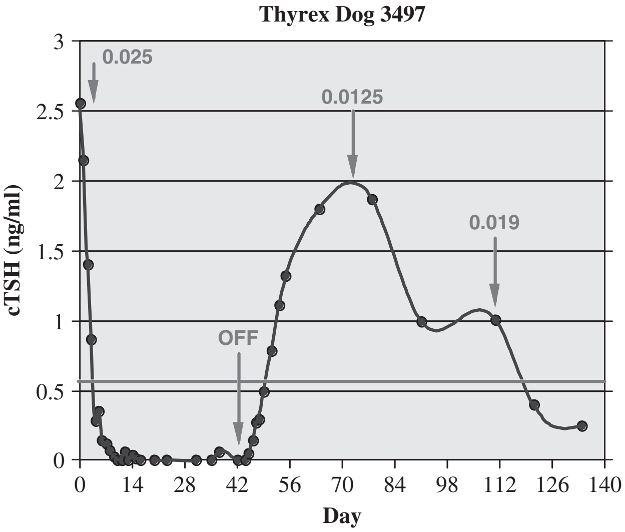

Figure 28.8 Effect of L-T_4 administration to a thyroidectomized dog on serum TSH concentrations. The numbers next to the arrows represent the dosage of L-T_4 administered once daily in mg/kg. Serum samples were taken 24 hours after the last dosing. On day 42, L-T_4 administration was terminated until day 70. The horizontal line represents the upper limit of the normal range for serum TSH concentration. Note the manner in which the varied L-T_4 dosage titrates the serum TSH concentration demonstrating the negative feedback system on the hypothalamus and pituitary.

concentrations at 4 or 6 hours after once-daily dosing, and some measure at "peak" and "trough" times. Animals on twice-daily administration probably can be checked at any time, but peak concentrations can be expected at the middle of the dosing interval (4–8 hours) and the nadir just prior to the next dose. Once the dog's dose is stabilized, once- or twice-yearly checks of serum T_4 (with or without T_3) concentrations are recommended.

Monitoring L-T_4 therapy may also be accomplished by documenting suppression of serum TSH. With the current generation of TSH immunoassays, concentrations are elevated only in about 75% of cases. Nonetheless, detectable TSH concentrations within the normal range still appear sensitive to titration of T_4 dosage (Figure 28.8). Another study demonstrated that serum TSH concentrations are suppressed for at least 24 hours following a single dose (Le Traon et al., 2009). Ninety percent of dogs evaluated chronically were managed successfully with once-daily dosing (van Dijl et al., 2014).

In a study of treatment of thyroidectomized dogs, it was shown that dosages as little as 0.02 mg/kg once a day will almost always suppress endogenous TSH concentrations into the normal or undetectable range. This observation establishes that the biological half-life of thyroid hormone exceeds by far the serum half-life (Ferguson and Hoenig, 1997). However, although titration of L-T_4 dosage by monitoring endogenous TSH concentrations is standard practice in hypothyroid human patients, no study has yet evaluated whether TSH suppression correlates consistently with a satisfactory clinical response in dogs. Therefore, it appears clear that dosing protocols recommending the dosage of 0.02 mg/kg twice daily probably reflect the dosage necessary for dogs with the lowest T_4 bioavailability. Unfortunately, the assay sensitivity does not allow the distinction of normal values from low values, so establishment of overtreatment and hyperthyroidism is not yet possible.

Although not recommended routinely, serum T_3 measurements following L-thyroxine administration should be interpreted together with the serum T_4 results and, most importantly, the clinical response. Low serum T_3 and T_4 concentrations, together with a poor clinical response, suggest an underdose or inadequate bioavailability (absorption). With T_3 administration, serum concentrations are reported to peak 2–3 hours after administration. Serum T_4 concentrations are routinely low or undetectable in dogs receiving T_3 therapy. Any remaining endogenous thyroidal T_4 secretion will be inhibited because of the suppression of pituitary TSH secretion by T_3 (Ferguson, 1986; Peterson and Ferguson, 1990; Rosychuk, 1982).

Therapeutic Failure

If clinical signs of hypothyroidism remain despite the use of reasonable doses of thyroid hormone, the following possibilities must be considered: (i) the dose or frequency of administration is improper; (ii) the owner is not complying with instructions or is not successfully administrating the product; (iii) the animal may not be absorbing the product well, or is metabolizing and/or excreting it too rapidly; (iv) the product is outdated; or (v) the diagnosis is incorrect. A syndrome of tissue resistance to thyroid hormone, while described in humans, has not yet been documented in the dog or cat.

Treatment of Myxedema Coma

Myxedema coma is a rare condition in domestic animals, only described in dogs, and is caused by severe untreated hypothyroidism. Often induced by an anesthetic episode or concurrent infectious disease, it results in severe mental obtundation or coma, and hypothermia. Common physical examination abnormalities include obesity and nonpitting edema (myxedema), and anemia and hypercholesterolemia are clinicopathological findings. Because of the extremely high mortality associated with this condition, it is essential that treatment be instituted promptly and vigorously as soon as the diagnosis is made. Treatment should include an intravenous dose of L-T_4 prepared for injection (100–200 µg total dose or 4–5 µg/kg), passive rewarming (wrapping in blankets, etc.), and mechanical respiratory support as needed.

Therapy for shock must include glucocorticoids and fluid and electrolyte replacement. Oral thyroxine therapy can be instituted when the animal stabilizes. A study of seven severely hypothyroid dogs treated with 4–5 μg/kg of L-T_4 IV observed improvement in mentation or ambulation and systolic hypotension within 30 hours of IV levothyroxine administration. Prognosis is good in most treated dogs (Pullen and Hess, 2006).

Antithyroid Drugs

Goitrogens

With the isolation and purification of thyroid peroxidase (TPO) enzyme of the thyroid gland, it became apparent that most compounds with antithyroid (goitrogenic) activity are inhibitors of TPO-catalyzed iodination. Plants of the genus *Brassica,* such as rutabaga, cabbage, and turnip, contain a compound called *goitrin* (see structure in Figure 28.9), which has antithyroid activity. In addition, plants such as broccoli and rapeseed include glucosinolates, which are metabolized to thiocyanate, an inhibitor of thyroid iodide uptake and organification. The so-called "cyanogenic glucosides," found in foods such as cassava, lima beans, and sweet potatoes, can be a source of cyanide, which then is detoxified to thiocyanate. Substituted phenols, such as resorcinol, phloroglucinol, and 2,4,dihydroxybenzoic acid, which may be found as contaminants in the water supply near coal conversion plants and may arise from degradation of flavonoids in plant material, also have goitrogenic activity (Taurog, 1991; Brucker-Davis, 1998; Cerundolo et al., 2009).

Studies have raised questions about the goitrogenic potential of environmental polyhalogenated aryl hydrocarbons (PHAHs), polychlorinated biphenyls (PCBs), polybrominated diphenyl ethers (PBDEs), plasticizer bisphenol A (BPA), and perchlorate on thyroid function. PHAHs have the particular potential to be retained by cats who have low glucuronyltransferase activity, and very high serum concentrations of PBDEs; dietary concentrations of BPA in cat food have been linked epidemiologically if not mechanistically to the development of feline hyperthyroidism. Confirmation of the link and the possible mechanisms still awaits further research (Edinboro et al., 2004; Dye et al., 2007; Mensching et al., 2007, 2012; Guo et al., 2012; Norrgran et al., 2015; Chow et al., 2015).

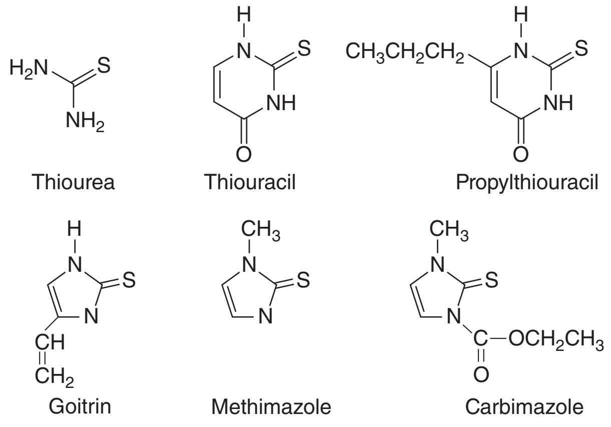

Figure 28.9 Thioureylene antithyroid drugs.

Thioureylenes or Thionamides

Antithyroid thioureylene or thionamide drugs are direct inhibitors of TPO, leading to a reduction in the organification and coupling steps of thyroid hormone synthesis. Figure 28.9 shows the structure of thiourea, goitrin, and the antithyroid drugs thiouracil, propylthiouracil, methimazole, and carbimazole. After administration, these drugs are actively concentrated by the thyroid gland, where they act to inhibit the synthesis of thyroid hormones through the following mechanisms: (i) blocking the incorporation of iodine into the tyrosyl groups in thyroglobulin; (ii) preventing the coupling of iodotyrosyl groups (mono- and diiodotyrosines) to form the ether linkage of T_4 and T_3; and (iii) direct interactions with the thyroglobulin molecule (Figure 28.1). Processes i and ii are mediated via inhibition of the enzyme TPO. Thionamide antithyroid drugs do not interfere with the thyroid gland's ability to concentrate, or "trap," inorganic iodine, do not block the release of stored thyroid hormone into the circulation, and do not damage the thyroid glandular tissue.

The thionamide drugs methimazole (MMI) and its prodrug carbimazole are currently the most commonly used antithyroid drugs in veterinary clinical practice (see Table 28.7 for products and dosages). Following initiation of treatment with MMI there is usually a slight delay in the fall of serum thyroid hormone concentrations as glandular hormone stores are becoming depleted. Another drug in this class, propylthiouracil (PTU), which has fallen out of favor due to autoimmune side effects in cats, has the additional mechanistic effect of blocking the conversion of T_4 to the more active T_3 in peripheral tissues like the liver and kidney. Therefore, serum T_4 may fall following both PTU and MMI therapy, but with MMI, due to autoregulatory mechanisms in the peripheral tissues (most likely up-regulation of D2 activity), serum T_3 is usually maintained within the normal range even when T_4 is quite low. As a result of this mechanism, it is rare to see a cat on MMI develop clinical signs of hypothyroidism. In some elderly hyperthyroid cats, elevations in serum creatinine with occasional overt renal failure develops. In cases where pretreatment renal function is in question, the use of MMI has gained favor because it provides a reversible and more gradual mode of therapy

Table 28.7 Antithyroid drugs

Drug	Product name	Dosage range and route (cats only)
Methimazole	Felimazole$^{\text{TM}}$; Tapazole$^{\text{TM}}$ (Jones Pharma), generic	Initial: 2.5–5 mg q 8–12 h PO Maintenance: 2.5–20 mg q 24 h or divided q 12 h
Carbimazole	Neomercazole$^{\text{TM}}$, Vidalta$^{\text{TM}}$, Neo-Carbimazole® zole®, Carbazole®, Neo Mercazole®, etc. (all only available in Europe and Canada)	Same as methimazole
Propylthiouracil	Propylthiouracil USP	50 mg q 8–12 h PO (generic)
Iopanoic acid	Telepaque$^{\text{TM}}$ (Amersham Health)	50 mg q 12 h PO (Note: dosage lowers serum T_3 only)
Potassium iodine (Lugol’s)		50 mg q 12–24 h PO

USP, US Pharmacopoeia.

for returning the animal to euthyroidism. It is now clear that the exacerbation of following therapy of hyperthyroidism is associated with posttreatment hypothyroidism identifiable by TSH concentrations above the normal range, observed in about one-third of cases in one study. Iatrogenic hypothyroidism was confirmed (low total T_4 and high TSH) in about 20% of cats. The incidence of increased creatinine concentrations was twofold higher (about 40%) in cats with elevated TSH compared to those with TSH within the reference range. The measurement of free T_4 by dialysis provided no additional information compared to measurement of total T_4 concentration (Aldridge et al., 2015). L-thyroxine supplementation helps to reduce exacerbation of azotemia in cats with hyperthyroidism and borderline renal disease (Broome et al., 2013).

Propylthiouracil

Propylthiouracil (PTU) is the prototype D1 inhibitor as well as being a TPO inhibitor. Despite its apparent additional therapeutic effects, the use of PTU has fallen out of favor because of its potential for serious side effects (Aucoin et al., 1985; Shenton et al., 2004). Like MMI, it can cause anorexia, vomiting, lethargy, and the development of positive antinuclear antibody titers, but has been associated with the development of autoimmune hemolytic anemia and immune-mediated thrombocytopenia. Because of the latter two complications, which are a particular problem in the animal being prepared for surgery, PTU can no longer be recommended for routine use in the hyperthyroid cat (Ferguson and Hoenig, 1991a; Ferguson et al., 1992; Kintzer, 1994; Peterson and Ferguson, 1990).

Methimazole

Methimazole is now the antithyroid medication of choice in the cat. The use of this drug in the cat has been well documented. In this study, doses as high as 5 mg q 8 h were applied, which reduced the serum T_4 into the normal range by 2–3 weeks. Since that time, most cats are diagnosed at an earlier phase of disease and MMI doses most commonly begin at 2.5 mg once or twice daily and are titrated upward in 2.5 mg (half tablet) intervals until the serum T_4 concentration falls within the lower half of the reference range. As mentioned, even cats with low serum T_4 may not become hypothyroid because the serum T_3 concentration generally remains normal. Once a satisfactory therapeutic effect is seen, many cats can be maintained on once-daily therapy, a major advantage for owner compliance. However, if a daily dose is missed, the serum T_4 concentration may rise rapidly. Cats on chronic MMI therapy should be checked at 1, 3 and 6 months to draw blood for serum T_4 measurement and to monitor for signs of drug toxicity (see below) (Peterson et al., 1988; Trepanier, 2007, 2015; Daminet et al., 2014).

Pharmacokinetics and pharmacodynamics of methimazole:
In euthyroid cats, the serum half-life has ranged from 4 to 6 hours following an IV dose. Following 2 weeks of oral methimazole, an average half-life of 3.4 hours was measured. In hyperthyroid cats, while the half-life was no different from euthyroid cats (2.3 hours), the mean residence time was shorter. Several studies in euthyroid and normal cats show bioavailability as averaging about 80%, with significant variability in bioavailability between animals. Studies in human hyperthyroid patients have shown that the drug has an intrathyroidal residence time of approximately 20 hours, which is fourfold longer than the serum half-life. Since antithyroid drugs act to inhibit thyroid hormone synthesis only after they are concentrated within the thyroid gland, serum half-life of these drugs may be of lesser importance than the intrathyroidal drug concentration for adequate control of the hyperthyroid state. There is usually a 1–3 week lag time between starting the drug and significant reductions in serum T_4 (Trepanier et al., 1991a, 1991b).

Adverse effects of methimazole:
Methimazole has been associated with the following adverse effects: anorexia (11.1%), vomiting (10.7%),

lethargy (8.8%), excoriations (2.3%), bleeding (2.3%), hepatopathy (1.5%), thrombocytopenia (2.7%), agranulocytosis (1.5%), leukopenia (4.7%), eosinophilia (11.3%), lymphocytosis (7.2%), positive antinuclear antibodies (ANA) (21.8%), and positive direct antiglobulin test (1.9%). The gastrointestinal adverse effects generally developed within the first month of treatment and usually resolved even with continued therapy.

Mild clinical side effects associated with methimazole treatment are relatively common (approximately 15% of cats) and include anorexia, vomiting, and lethargy. In most cats, these adverse signs are transient and resolve despite continued administration of the drug. Severe gastrointestinal signs persist in some cats, however, necessitating discontinuation of the drug. Self-induced excoriations of the face and neck also may develop in a few cats within the first 6 weeks of therapy. Although these cutaneous lesions tend to be partially responsive to treatment with systemic glucocorticoids, cessation of methimazole administration is usually required for complete resolution of these excoriations. Finally, hepatic toxicity is an uncommon but serious reaction that can develop during drug treatment. Methimazole-induced hepatopathy is characterized by the development of marked increases in serum concentrations of alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (SAP), and total bilirubin. Clinical improvement, with resolution of anorexia, vomiting, and lethargy, usually occurs within a few days after cessation of methimazole, but jaundice and abnormal serum biochemical tests indicative of liver disease may not resolve for several weeks. Rechallenge with the drug will again induce clinical signs and serum biochemical abnormalities indicative of hepatic disease within a few days. A variety of hematological abnormalities may develop in cats during treatment with methimazole. Those abnormalities that do not appear to be associated with any adverse effects include eosinophilia, lymphocytosis, and transient leukopenia with a normal differential count. As with PTU treatment, more serious hematological reactions that develop in a few cats treated with methimazole include severe thrombocytopenia (platelet count <75,000 cells/mm^3) and agranulocytosis (severe leukopenia with a total granulocyte count <250 cells/mm^3). Most cats that develop severe thrombocytopenia also show concomitant overt bleeding (i.e., epistaxis, oral hemorrhage). Development of agranulocytosis during methimazole treatment predisposes to severe bacterial infections, systemic toxicity, and fever. If serious hematological reactions develop during methimazole therapy, the drug should be stopped and supportive care given; these adverse reactions should resolve within 5 days after the methimazole is withdrawn. Since most life-threatening side effects (e.g., hepatopathy, thrombocytopenia, agranulocytosis) caused by methimazole treatment usually again develop quickly after rechallenge with the drug, alternative therapy with either surgery or radioiodine should be considered in these cases.

During methimazole therapy, serum ANA develop in a high percentage of cats after treatment with methimazole. The risk of developing ANA appears to increase with the duration of methimazole treatment, with ANA developing in approximately half of cats treated for greater than 6 months. The risk of developing serum ANA also appears to be greater for cats treated with higher daily methimazole doses, since most cats that develop ANA are receiving doses ≥15 mg/day and ANA will disappear in most cats after the dosage is decreased. Despite the high prevalence of ANA development during long-term treatment with methimazole, clinical signs associated with a lupus-like syndrome (i.e., dermatitis, polyarthritis, glomerulonephritis, hemolytic anemia, or fever) have not been observed in any of these cats. The daily drug dosage should therefore be decreased to as low as possible (while still maintaining serum T_4 values within the low normal range), since ANA tests will become negative in many cats when the methimazole dosage is decreased (Peterson et al., 1988; Daminet et al., 2014; Trepanier, 2015).

Transdermal Methimazole

Methimazole compounded in a pluronic lecithin organogel (PLO) dosage form has begun to be offered by compounding pharmacists. Transdermal pluronic gels have been shown to modulate permeation of a variety of drugs from small organics to peptides. Lecithin is an emulsifying agent that increases fluidity of stratum corneum, and can result in exfoliation and low-grade inflammation, resulting in greater absorption when given chronically. Transdermal administration may be considered when oral therapy of MMI is impractical in a cat. Although a pharmacokinetic study initially showed poor to no bioavailability for methimazole formulated in PLO and administered as a single dose inside the pinna of healthy cats, studies of daily administration to hyperthyroid cats for 4 weeks have reported clinical response and reduction of serum T_4 concentrations. The time to optimal reduction of serum T_4 response to treatment tends to be slower than with oral therapy. Furthermore, the response is more variable, possibly because of greater variability in factors determining transdermal bioavailability. Despite questionable absorption in euthyroid cats following a single dose, a study by Sartor et al. (2004) evaluated the efficacy and safety of transdermal MMI in 47 hyperthyroid cats. A randomized clinical trial compared transdermal with oral MMI at 2.5 mg q 12 h for both routes. While 88% of cats treated by oral route had serum T_4 concentrations within the reference range after 2 weeks, 56% of transdermally treated cats reached this goal. This efficacy gap reduced to 80% with oral administration and 67% by transdermal administration (not significant). Oral MMI cats had a higher incidence of gastrointestinal (GI) adverse effects (24%) compared to the cats treated with transdermal methimazole (4%), but no differences were found between groups in the incidence of other side effects. In this study, the absolute bioavailability (compared to IV route) was 40% for the oral and transdermal routes. Another study of 13 hyperthyroid cats given 5 mg/0.1 ml of MMI q 12 h showed that total T_4 concentrations fell to 28% of baseline at 14 days and 15% of baseline (low normal range) at 28 days. The gastrointestinal side effects also appeared reduced with the transdermal route (Lecuyer et al., 2006). Another study of a new lipophilic formulation had about half the relative bioavailablity compared to a similar dose of carbimazole (see Section Carbimazole) (Hill et al., 2014).

More recent studies utilized a starting dose of 2.5 mg per cat q 12 h and 5 mg per cat q 24 h). Significantly decreased T_4 concentrations were observed in weeks 1 and 3. All cats showed sustained suppression of T_4 concentration during the 10-hour period in both daily and twice daily dosing regimens. As a result, sampling time for T_4 measurement does not seem to be critical. However, it seems difficult to keep the T_4 concentrations constantly within the reference interval. Median follow-up time was almost 2 years with daily doses ranged from 1 to 15 mg. Higher doses can be expected after prolonged treatment and, despite greater convenience for the owner, compliance should be regularly evaluated (Boretti et al., 2013, 2014).

Methimazole, Thyroid Scintigraphy, and Subsequent Ablative Radioiodide Therapy

Studies are conflicting about whether concurrent methimazole affects results of diagnostic scintigraphy. One study demonstrated that ^{123}I uptake is not inhibited by MMI treatment in normal cats, but is significantly increased after withdrawal with peak uptake between 4 and 9 days after discontinuation of MMI. Increased uptake of [$^{99m}TcO_4$] may also affect the interpretation of [$^{99m}TcO_4$] thyroid scintigraphy for 2–3 weeks (Nieckarz and Daniel, 2001). These scintigraphic findings are likely an artifact of seeing intense pertechnetate uptake in large hyperfunctional thyroid nodules, and then, upon reduction of T_4, the increase of TSH would stimulate the normal tissue or less active tissue to take up [$^{99m}TcO_4$.] Another study saw no effect, but also did not see TSH rise in most cats (Fischetti et al., 2005). Some hyperthyroid cats can be diagnosed by thyroid scan as having unilateral disease before MMI treatment, and then, once euthyroid on therapy, can appear on thyroid scan to have bilateral disease (Peterson and Broome, 2015).

Monitoring Patients on Methimazole

In addition to serum total T_4 or possibly even TSH concentrations, the following liver function tests are recommended: ALT, SAP, and/or AST, and total bilirubin. Alkaline phosphatase is likely high in hyperthyroidism because of an elevation of the bone isoenzyme associated with increased calcium turnover. Renal function tests including blood urea nitrogen (BUN) and creatinine concentrations are important in the first month of treatment to monitor the effect of correction of hyperthyroidism on reduction of glomerular filtration rate (GFR). Complete blood count (CBC) and platelet count should be periodically monitored as peak chance of autoimmune phenomena is at about 3 months of therapy (Peterson et al., 1988; Trepanier, 2007; Rutland et al., 2009; Daminet et al., 2014).

Carbimazole

The antithyroid drug carbimazole is a carbethoxy derivative of methimazole that is rapidly and completely metabolized to the parent compound, which is responsible for its antithyroid activity. It is commonly used in treatment of feline hyperthyroidism outside of North America. Carbimazole is a larger molecule than methimazole; 10 mg of carbimazole is equimolar to 6 mg methimazole. To achieve the same effect with carbimazole as with methimazole, approximately twice the dosage of carbimazole would be required. Clinical experience in Europe describes fewer gastrointestinal side effects for this medication likely because this prodrug reduces direct contact of methimazole on gastrointestinal mucosa. Transdermal administration of MMI has also been associated with lower gastrointestinal side effects (Peterson and Becker, 1984; Trepanier, 2007;Frenais et al., 2008, 2009; Daminet, 2014). A controlled release carbimazole tablet was developed, and results of a crossover study demonstrated that the pharmacokinetics of methimazole with a single dose of this prodrug may be similar to those with a single dose methimazole tablet given at an identical molar dose (Longhofer et al., 2010).

Medical Options to Thionamide Drugs

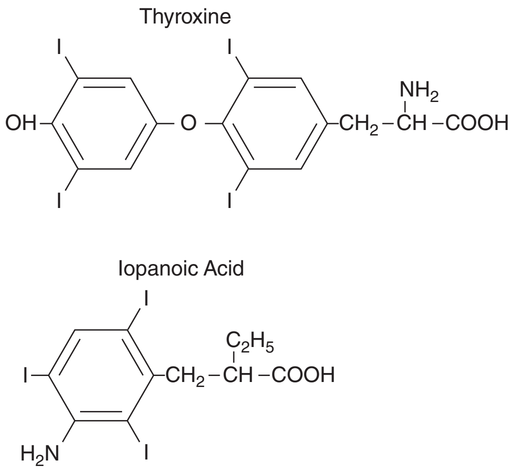
When cats have adverse reactions to the thionamides, if the reaction is gastrointestinal, often a reduction of the dosage or conversion to carbimazole or transdermal therapy will reduce side effects (see Sections Transdermal Methimazole and Carbimazole). However, if the reaction is an allergic one, the antithyroid drug class must be changed if medical therapy is still going to be pursued. PTU and carbimazole, as thionamides with similar structure, would not then be an option; transdermal therapy with methimazole would also not be an option.

Iodinated Radiocontrast Agents

In human medicine, iodinated radiocontrast agents have been employed as adjunctive antithyroid drugs. These agents have several potential mechanisms of action:

1) *Release of iodide, which can transiently suppress thyroid secretion through the Wolff–Chaikoff effect.* This effect seems insignificant in cats as serum T_4 concentrations rarely fall with these agents; however, the effect should be considered if therapy is to precede ^{131}I treatment.
2) *Direct inhibition of both D1 and D2 enzymes reducing the production of more bioactive T_3.* This effect appears to be the most dramatic effect in cats, and efficacy is best monitored by documenting the reduction of serum T_3 into the normal range despite an elevated serum T_4 concentration
3) Inhibition of uptake and/or nuclear receptor binding of T_3. This mechanism has not been documented in cat tissues.

The first such agent used in managing feline hyperthyroidism was the biliary contrast agent, ipodate, which was shown in both experimental hyperthyroidism and in spontaneously hyperthyroid cats to be an alternative medical treatment for patients not tolerating MMI or PTU. In a study of cats in which hyperthyroidism was experimentally induced by the administration of T_4, ipodate significantly reduced the serum T_3 concentrations and was well tolerated by otherwise healthy cats (Chopra et al., 1984; Ferguson et al., 1988; Murray and Peterson, 1997). Ipodate was removed from the market several years ago and has largely been replaced in veterinary use by iopanoic acid. Iopanoic acid contains three iodines and is 67% iodine by weight (Figure 28.10). The dose of 50 mg q 12 h was confirmed in experimentally induced hyperthyroidism and applied in spontaneously hyperthyroid cats. In spontaneously hyperthyroid cats, mean T_3 concentrations fell at all time points and serum T_4 concentrations rose at 1 and 3 months of therapy. The authors concluded that iopanoic acid be useful for acute, but not chronic management of hyperthyroidism (Gallagher and Panciera, 2009, 2011).



Thyroxine

Iopanoic Acid

Figure 28.10 Comparison of structure of radiocontrast agent iopanoic acid to L-thyroxine.

Radioactive Iodine (^{131}I) Therapy

Although only available in specialty referral centers, radioiodine treatment is the most effective and selective cure for toxic goiter in the cat because it selectively destroys the functioning thyroid tissue after being taken up and incorporated into thyroid hormone precursors in the thyroid gland. There is rarely, if ever, damage to the nearby tissue responsible for regulating serum calcium by the secretion of parathyroid hormone and calcitonin. Iodine-131 has a half-life of 8 days and produces both gamma and beta radiation. The beta particles, with a short path length, serve to produce most of the local tissue destruction. Radioiodine is also used in much higher doses in an attempt to ablate thyroid adenocarcinomas in cats and dogs. Following a therapeutic dose (generally 1–5 mCi) of ^{131}I, the serum T_4 and T_3 concentrations will commonly normalize within 1 to 2 weeks. The major disadvantage of radioiodine therapy is that certain radiation safety precautions must be taken. Radioiodine is secreted in saliva, and excreted in urine and feces. As such, handling of the cat's haircoat or waste may result in contamination. Unlike human patients who may receive therapeutic doses on an outpatient basis, radioiodine-treated cats must be hospitalized for periods of time (3 days to 4 weeks), which depend upon the dose administered and the state's radiation safety regulations. Despite these drawbacks, radioiodine therapy is the least invasive cure for bilateral adenomatous goiter, has no hypoparathyroidism or toxicity associated with it, and can be implemented without anesthesia or sedation, an important consideration in the elderly cat with other medical complications (Kintzer, 1994; Kintzer and Peterson, 1991; Meric et al., 1986).

Regarding the efficacy and prognosis for survival following radioiodide therapy, a study of 231 cats being treated with ^{131}I was performed (Slater et al., 2001). With a mean age at diagnosis of 13 years, the treated cats had a median survival time of 25 months. Hypothyroidism was present in five cats (2.2%), and hyperthyroidism was present in one (0.4%). While there was a 33% incidence of renal disease after treatment, it was not clear how many cats might have had this problem at diagnosis (Peterson and Becker, 1995; Peterson, 2006).

Thyroid Imaging

Thyroid imaging is performed using radioactive iodine or $^{99m}TcO_4^-$ (pertechnetate), which is taken up by mechanisms similar to iodide, but is not incorporated into iodothyronines on thyroglobulin. Because of its rapid uptake and increased safety, technetium can be given in higher diagnostic doses and provides a better image than radioiodine. In cats with palpable goiter but normal serum total T_4 and/or free T_4 concentrations, a semiquantitative thyroid scintigraphy is a more sensitive method for confirmation of disease. With this assumption, Daniel and coworkers (2002) used this approach to quantify pertechnetate uptake in 43 cats with hyperthyroidism and eight normal control cats. The 20-minute thyroid : salivary ratio of the most intense lobe correlated best with serum T_4 concentrations, and the authors concluded that this ratio was a valuable predictor of the thyroid status. In a study of over 2000 cases of suspected feline hyperthyroidism, thyroid-to-salivary (T/S) gland ratios >1.5 or thyroid-to-background (T/B)ratios of >6.1 were established as specific diagnostic criteria (Peterson and Broome, 2015). Of this series, 99% had high T/S ratios and 96% had high T/B ratios, 32% had unilateral disease, 63% had bilateral disease, and 4% had multifocal disease. Ectopic lingual or mediastinal disease was established in 4%, and carcinoma was suspected (not proven) in 2% (Kintzer, 1994; Kintzer and Peterson, 1991; Peterson and Broome, 2015).

Glucocorticoids, Mineralocorticoids, and Adrenolytic Drugs

Duncan C. Ferguson and Margarethe Hoenig

Glucocorticoids

Glucocorticoids (GCs) are among the most widely used (and misused) class of drugs in veterinary medicine. In recent years, more has been learned about the actions and adverse effects in a variety of species but, nonetheless, the depth of scientific information on optimal glucocorticoid dosages and dosing intervals in many species is still quite variable as species differences in metabolism and action exist. Therefore, therapeutic protocols are often the product of clinical experience, common sense, and information from human medicine, or from another species. Though the following discussion emphasizes systemic use of glucocorticoids, it should be recognized that local application (ophthalmic, otic, intraarticular, topical, intralesional) also has similar systemic effects.

Management Of Hypoadrenocorticism

Spontaneous glucocorticoid deficiency without concomitant mineralocorticoid deficiency is a relatively rare occurrence in dogs, the species that most commonly suffers from Addison's disease (gluco- and mineralocorticoid deficiency). The underlying cause is suspected to be an immune-mediated destruction of the adrenal cortex, making replacement of the physiological hormones aldosterone and cortisol (in most domestic animals) to be the primary clinical goal. Spontaneous selective glucocorticoid deficiency is rare; however, exogenous glucocorticoids may themselves induce selective atrophy of the glucocorticoid-producing part of the adrenal cortex (zonae fasciculata and reticularis) (Addison, 1855; Ferguson, 1985a; Ferguson et al., 1978; Hoenig and Ferguson, 1991b).

Management of Nonadrenal Disorders: Inflammatory, Allergic, and Autoimmune Disorders

Glucocorticoids are potent antiinflammatory and immunosuppressant agents. The majority of therapeutic applications for these agents fall into these classifications. However, the adverse metabolic effects, as described in Section Toxicity, are difficult to separate pharmacologically from the therapeutic benefits, making glucocorticoids potent, yet potentially dangerous, compounds. The cellular basis for the action of these hormones has recently become clearer and has given rise to new pharmaceutical classes where the antiinflammatory/immunosuppressive and metabolic effects, for example, can be dissociated (see Section Newer Preparations) (Schäcke et al., 2007; Barnes, 2010; Hasselgren et al., 2010; Vandevyver et al., 2013).

Review Of Physiology

Biosynthesis of Steroids

The adrenal cortex synthesizes a variety of steroids from cholesterol and releases them into the circulation. Those steroids with effects on intermediary metabolism are termed "glucocorticoids" and are produced mainly in the layers of the adrenal gland called the *zonae fasciculata* and *reticularis*. The steroids with primarily salt-retaining activity are called *mineralocorticoids* and are synthesized in the zona glomerulosa. The adrenal gland is also capable of synthesizing steroids with androgenic and estrogenic activity. The major glucocorticoid in most domestic animals is cortisol, and in most mammals, the most important mineralocorticoid is aldosterone. In some species (e.g., the rat), corticosterone is the major glucocorticoid. It is less firmly bound to protein and therefore metabolized more rapidly. Quantitatively, dehydroepiandrosterone (DHEA) is the major androgen, with part of it being sulfated to DHEA-sulfate. Both DHEA and androstenedione are very weak androgens. A small amount of testosterone is secreted by the adrenal gland and may be of greater importance as an androgen. Little is known about the estrogens secreted by the adrenal gland. However, the adrenal androgens such as testosterone and androstenedione can be converted to estrone in small amounts by nonendocrine tissues (Aron and Tyrrell, 1994; Tyrrell et al., 1994).

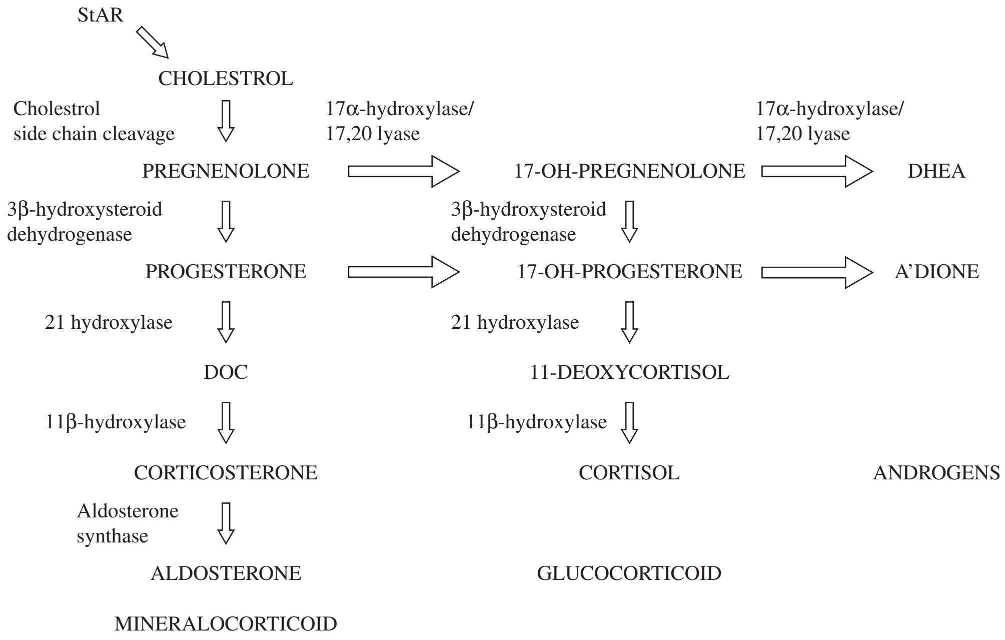

Figure 29.1 Adrenal steroidogenesis. Steroidogenic acute regulatory (StAR) protein mediates uptake of cholesterol into mitochondria within adrenocortical cells. Then aldosterone, cortisol, and adrenal androgens are synthesized through a series of steroidogenic enzymes. A'dione, androstenedione; DHEA, dehydroepiandrosterone; DOC, deoxycorticosterone. Source: Stewart, 2003. Reproduced with permission of Elsevier.

The biochemical pathways involved in adrenal steroidogenesis are shown in Figure 29.1. The initial adrenocorticotropic hormone (ACTH)-dependent rate-limiting step is the transport of intracellular cholesterol from the outer to the inner mitochondrial membrane by steroidogenic acute regulatory (StAR) protein, where it is then converted to pregnenolone by cytochrome P450scc (SCC; side-chain cleavage enzyme). The synthesis of the various adrenal steroids then involves a series of cytochrome P450 enzymes (Table 29.1). SCC and the CYP11B enzymes are localized to the mitochondria and utilize a specific electron shuttle system to hydroxylate steroids. 17α-hydroxylase and 21-hydroxylase are localized in the endoplasmic reticulum. In the cytoplasm, pregnenolone is converted to progesterone by 3β-hydroxysteroid dehydrogenase (3β-HSD), which is the target of the antiadrenal drug trilostane. Progesterone is hydroxylated to 17- hydroxyprogesterone (OHP) by 17α-hydroxylase, and this step is necessary for glucocorticoid synthesis. 21-hydroxylation of either progesterone in the zona glomerulosa or 17-OHP in the zona fasciculata is accomplished by 21-hydroxylase, yielding deoxycorticosterone (DOC) or 11-deoxycortisol, respectively. Cortisol is then synthesized in the mitochondria by the conversion of 11-deoxycortisol to cortisol by the enzyme 11-β-hydroxylase. In the zona glomerulosa, 11β-hydroxylase also converts DOC to corticosterone. Aldosterone synthase also accomplishes this reaction and converts corticosterone to aldosterone through the intermediate 18-OH corticosterone.

Table 29.1 Nomenclature for adrenal steroidogenic enzymes and their genes. Source: Adapted from Stewart, 2003. Reproduced with permission of Elsevier.

Enzyme name	Gene
Cholesterol side-chain cleavage (SCC) (desmolase)	*CYP11A1*
3β-hydroxysteroid dehydrogenase (3β-HSD) (type II isozyme)	*HSD3B2*
17α-hydroxylase/17,20 lyase	*CYP17*
21-Hydroxylase	*CYP21A2*
11β-Hydroxylase	*CYP11B1*
Aldosterone synthase	*CYP11B2*

Adrenal steroids are metabolized in extradrenal tissues as well, and prereceptor enzyme-mediated metabolism of glucocorticoids adds another layer of metabolic control. Cortisol is interconverted with biologically inactive cortisone by the 11-β-hydroxysteroid dehydrogenase system (11-β-HSD). The conversion of inactive 11-ketoglucocorticoids cortisone and 11-dehydrocorticosterone into active 11-β-hydroxyglucocorticoids (cortisol and corticosterone, respectively) is catalyzed by 11-β -HSD1 using NADPH. This enzyme is prominent in metabolically active tissues such as the liver, skeletal muscle, and fat. Likewise, the synthetic glucocorticoid prednisone must be converted by 11-β-HSD1 in the liver for bioactivity (Stewart, 2003). Conversely, 11-β-HSD2 uses NAD^+ to convert cortisol

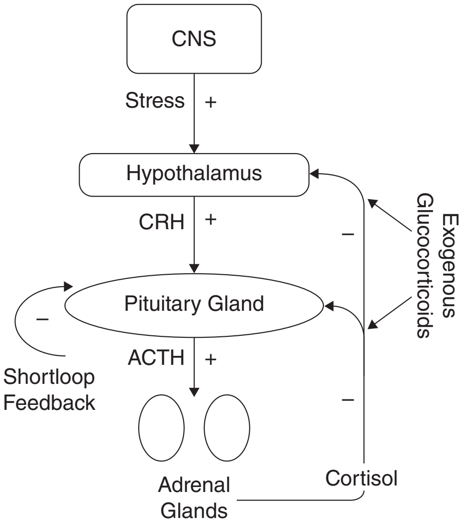

Figure 29.2 Hypothalamic–pituitary–adrenal axis. Exogenous glucocorticoids inhibit the hypothalamic and pituitary function in a negative-feedback fashion. ACTH, through "short-loop" feedback, inhibits its own production. Therefore, recovery of the entire hypothalamic–pituitary–adrenal axis requires withdrawal of glucocorticoid and is not enhanced by the administration of exogenous ACTH. CNS, central nervous system; CRH, corticotropin-releasing hormone; ACTH, adrenocorticotropic hormone; + represents stimulation; – represents inhibition.

to cortisone, essentially inactivating it. In the distal renal tubules, this enzyme inactivates cortisol ensuring that only aldosterone is an agonist at the mineralocorticoid receptors (Atanasov and Odermatt, 2007; Divari et al., 2011; Chapman et al., 2013). The placenta and fetus also express 11-β-HSD2, thereby preventing premature developmental programming that might otherwise be caused by cortisol.

Hypothalamic–Pituitary–Adrenal Axis

Production of ACTH is stimulated by corticotropin-releasing hormone (CRH), which is a hypothalamic hormone (Figure 29.2) (see also Chapter 26); production of ACTH is also influenced by vasopressin (antidiuretic hormone; ADH), particularly during stress. There is also central nervous system (CNS) input into hypothalamic hormone secretion. A "short-loop" feedback system of ACTH on the corticotrophs (ACTH-producing cells) in the pituitary has also been described. In humans, cortisol is secreted in response to pulsatile ACTH release with diurnal variation.

Negative feedback of glucocorticoids on ACTH secretion occurs at both the hypothalamic and pituitary levels via two mechanisms:

1) ”Fast feedback” is sensitive to the rate of change of cortisol levels and likely occurs without interaction with nuclear steroid receptors (see Section Cellular Mechanisms of Negative Feedback).
2) "Slow feedback" is sensitive to the absolute cortisol concentration and is a nuclear receptor–mediated effect, which results in a decrease in ACTH synthesis. The clinical test for spontaneous hyperadrenocorticism, called the dexamethasone suppression test, is mediated by this mechanism of feedback (Keller-Wood, 1990; Tyrrell et al., 1994).

Pharmacological doses of glucocorticoids have a profound effect on endogenous glucocorticoid regulation, suppressing both hypothalamic and pituitary hormone production (Figure 29.2). Cortisol inhibits ACTH secretion and CRH secretion through negative feedback at both hypothalamic and pituitary levels, a point that is important when considering recovery of the hypothalamic–pituitary–adrenal axis (HPAA) from exogenous glucocorticoid administration.

Glucocorticoids with antiinflammatory effects but no effects on the HPAA have not been identified to date. As a result, long-term use of supraphysiological doses may lead to adrenocortical atrophy and decreased adrenal secretory reserve (Chastain et al., 1981; Chastain and Graham, 1979; Hench, 1952; Kemppainen et al., 1982; Moore and Hoenig, 1992).

Cellular mechanisms of negative feedback: Glucocorticoids inhibit pro-opiomelanocortin (POMC) gene transcription (and therefore ACTH synthesis and secretion) in the anterior pituitary and CRH and vasopressin (AVP) mRNA synthesis and secretion in the hypothalamus. This negative feedback is dependent upon the dose, potency, half-life, and duration of administration of the glucocorticoid administered. Although feedback inhibition is principally mediated by the glucocorticoid receptor (GR), there is evidence of fast-loop feedback, which can account for as much as 50% of the negative feedback effect. Glucocorticoids have shown negative effects on spiking of periventricular nucleus (PVN) neurons in the hypothalamus by an effect blocked by a glucocorticoid receptor antagonist. However, GCs also acutely suppress voltage-activated K^+ currents of PVN neurons, and inhibit glutamatergic excitatory postsynaptic currents by PVN neurons within minutes. This effect appears to be due to the release of endocannabinoids, which suppress in a retrograde fashion the presynaptic release of glutamate and γ-amino butyric acid (GABA). Furthermore, GCs induce a rapid facilitatory effect on GABA release by these hypothalamic neurons. There is some evidence that the membrane-bound GRs mediating these rapid effects engage directly or indirectly the Gs-adenylate cyclase-PKA signaling pathway. The combined effect of suppression of excitatory synaptic input with facilitation of inhibition of PVN neurons results in rapid inhibition of PVN output controlling the HPAA (Di et al., 2003; Tasker et al., 2006).

Therapeutic significance: The pattern of glucocorticoid presentation influences gene regulation and tissue responses: pulsatility is an important factor for regulation of the HPAA and of tissue responses to glucocorticoids (Russell and Lightman, 2014). In humans, single daily doses of exogenous glucocorticoids are most commonly recommended to be given in the morning to mimic the adrenal gland's secretory pattern (Tyrrell et al., 1994). Although older reports claimed the existence of a diurnal cortisol variation in dogs and cats, with plasma cortisol level peaking in the morning in dogs and in the evening in cats, carefully designed studies have not confirmed these observations (Kemppainen, 1986). Under basal (nonstressful) conditions, the adrenal gland produces cortisol (hydrocortisone) at about 1 mg/kg body weight daily in most species.

Plasma Binding, Metabolism, and Excretion

In plasma, cortisol is over 90% bound to plasma proteins. The remaining 10% free hormone is the active moiety according to the free-hormone hypothesis. Corticosteroid-binding globulin (CBG), an α_2 globulin synthesized by the liver, binds the majority of circulating hormone under normal circumstances. The remainder is free or loosely bound to albumin and is available to exert its effect on target cells. Cortisol is removed from the circulation by the liver, where it is reduced and conjugated to form water-soluble glucuronides and sulfates, which are excreted into the urine (Aron and Tyrrell, 1994; Grote et al., 1993; Hammond, 1990; Tyrrell et al., 1994).

Molecular Mechanisms of Action

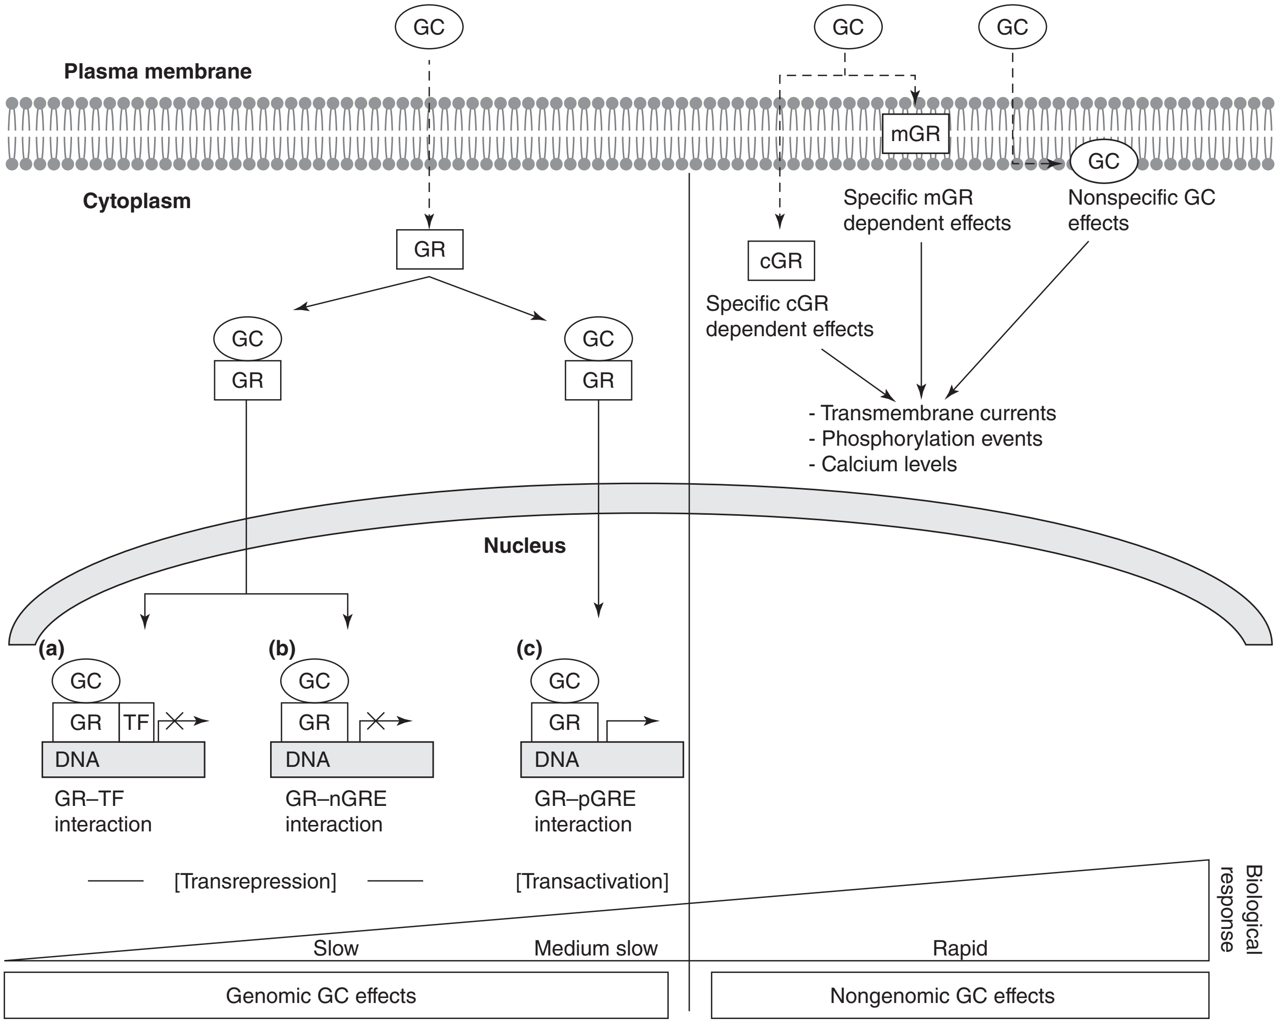
Glucocorticoids have four cellular mechanisms of action: (i) the classical genomic mechanism of action caused by the cytosolic glucocorticoid receptor (cGR); (ii) secondary nongenomic effects also initiated by the cGR; (iii) membrane-bound glucocorticoid receptor (mGR)-mediated nongenomic effects; and (iv) nonspecific, nongenomic effects caused by interactions with cellular membranes (Figure 29.3; Loewenberg et al., 2007). Which of these effects is seen will depend upon the tissue and the dose of glucocorticoids (Table 29.2) (Stahn et al., 2007; Buttgereit, 2004).

Genomic Mechanisms of Action

Genomic mechanisms mediate most effects associated with eventual protein synthesis, such as low-dose physiological replacement therapy and antiinflammatory and immunomodulatory effects; however, it is now clear that some effects, particularly the more rapid ones seen at high glucocorticoid doses, cannot be explained through this mechanism (see Section Nongenomic Effects of Glucocortoids). The genomic mechanisms of glucocorticoid action are cGR-mediated by the cytoplasmic glucocorticoid receptor. The unliganded cGR is a 94-kD protein that exists in the cytoplasm as a multiprotein complex including heat-shock proteins (Hsp), such as Hsp90, Hsp70, Hsp56, and Hsp40. There is also an interaction with immunophilins, (chaperones such as p23 and Src) and several kinases in the mitogen-activated protein kinase (MAPK) signaling system. The glucocorticoid receptor itself consists of three domains: an N-terminal domain containing transactivation functions, a DNA-binding domain with a "zinc-finger" motif, and a glucocorticoid-binding domain. Binding to the cGR ultimately induces (also known as *transactivation*) or inhibits (also known as *transrepression*) the synthesis of regulatory proteins. The genomic effects are generally not observed prior to 30 minutes because of the time necessary for cGR activation/translocation, transcription, and translation. It is estimated that glucocorticoids influence the transcription of ~1% of the entire genome either directly or indirectly through interaction with transcription factors and coactivators (Stahn et al., 2007).

Genomic effects via the cytosolic glucocorticoid receptor (cGR): The cholesterol-like structure and low molecular weight (~300 daltons) allow GCs to pass easily through the cell membrane and bind to the inactive cGR. Conformational changes in the GC/cGR complex result in dissociation from heat shock proteins (HSPs) 70 and 90 followed by migration within 20 minutes to the nucleus. Binding occurs as a homodimer to the glucocorticoid response element (GRE) in association with the activator protein-1 (AP-1) comprised of *c-fos* and *c-jun*. Binding of the GC/cGR to a positive GRE (pGRE) results, for example, in induced synthesis of antiinflammatory proteins (e.g., lipocortin 1, IκB, annexin-1, MAP kinase phosphatase 1, and IL-10), as well as metabolic proteins (e.g., those key to gluconeogenesis) often associated with common side effects. Transcription of genes can be inhibited by GCs via direct interaction between the GR and negative GREs (nGRE), such as those associated with pituitary expression and secretion of pro-opiomelanocortin, the precursor to ACTH, which constitutes the negative feedback system in the pituitary (see Figures 29.2, 29.3) (Loewenberg et al., 2007).

Glucocorticoids also suppress expression of inflammatory genes, including interleukin 1 and 2 (IL-1 and IL-2) via the same mechanism (Loewenberg et al., 2007; Stahn et al., 2007). The repressive effect of GR on nuclear factor-κB (NF-κB) regulation is balanced by the NF-κB negative regulation of GR α–mediated transcription, although the mechanism underlying such antagonism is as yet unclear (Duma et al., 2006). Transcription factors may also be displaced from a positive GRE through direct interaction of the factor and the GR. In addition, GR-mediated transcriptional modulation can be achieved through direct protein–protein interaction with proinflammatory transcription factors, such as activator protein-1 (AP-1),



TRENDS in Molecular Medicine

Figure 29.3 Genomic and nongenomic cellular mechanisms of glucocorticoid (GC) action. GCs diffuse into cells and bind to the cytoplasmic GR, after which the GC–GR complex translocates into the nucleus.
Left side of figure: (a) Ligated GR directly inhibits proinflammatory transcription factors such as AP-1,NF-κB and STAT (b) Ligated GR actively suppresses transcription (transrepression) of inflammatory genes (such as IL-1 and IL-2) through binding to negative GREs (nGREs). GC-induced transrepression is slow because time is required before RNA and protein levels of target genes are fully degraded. (c) Activated GR induces transcription (transactivation) of immunosuppressive genes (e.g., lipocortin-1) via positive GREs (pGREs). Transactivation of genes that encode regulator proteins is less slow (medium slow) compared to transrepression.
Right side of figure: GCs induce rapid effects (occurring within minutes) on transmembrane currents, signal transduction (such as MAPK signaling pathways), second-messenger cascades, or intracellular Ca^{++} mobilization. Nongenomic GC effects are mediated by cytosolic or membrane-bound GRs, or via nonspecific interactions with cell membranes.
In this simplified scheme, no GR–chaperones are depicted.

NF-κB, or signal transducers and activator of transcription (STAT), leading to inhibition of target gene expression (van der Velden, 1998; Loewenberg et al., 2007).

Selective glucocorticoid receptor modulators (SEGRMs) and agonists (SEGRAs): Undesirable effects of GC therapy have generally been ascribed to dimer-mediated transactivation, while beneficial antiinflammatory effects are due to monomer-mediated transrepression of the GR. However, dimer-mediated transactivation is now known to be essential to antiinflammatory activity (Vandevyver et al., 2013). Dissociated GR-ligand agonists (DIGRAs), now preferably called selective glucocorticoid receptor agonist modulators (SEGRAMs, SEGRAs, or SEGRMs), are experimental drugs in development designed to share desirable effects of glucocorticoids with fewer side effects (Schäcke et al., 2007). To the author's knowledge, none have yet made it to veterinary use.

Table 29.2 Current knowledge on the relationship between clinical dosing and cellular actions of glucocorticoids. Source: Adapted from Buttgereit et al., 2004. Reproduced with permission of John Wiley & Sons.

Daily prednisolone dosage (mg/kg)	Therapeutic application	Genomic actions (% receptor saturation)	Nongenomic nonspecific	Nongenomic cGR-mediated
Low (≤0.2)	Replacement or low maintenance Antiinflammatory	+ (<50%)	–	?
Medium (0.2–0.5)	Initial Antinflammatory (chronic disease)	++ (50–100%)	(+)	(+)

Very high (1–3)	Acute antiinflammatory or life-threatening immunosuppressive	+++ (almost 100%)	+++	++
Pulse or shock therapy (≥3)	Very severe or life-threatening Immunosuppressive or initial lymphocytolytic	++++ (100%)	++++	+++

cGR, cytosolic glucocorticoid receptor.
?, unknown; –, not relevant; (+), perhaps relevant, but of minor importance; +, relevant; ++, relevant to very relevant; +++, very relevant; ++++, most relevant.

Mechanism of action (Figures 29.4): Negative regulation by the GR is associated with inhibition of transcription factor activity (generally proinflammatory) through tethering to such factors. GR homodimer binding to the GRE causes histone acetylation resulting in chromatin remodeling and the association of RNA polymerase II through recruitment of coactivator proteins with acetyltransferase activity, leading to transactivation (e.g., cyclic AMP-responsive element-binding protein). However, when homodimeric GR binds to the negative GRE, either by displacing coactivators or via recruitment of corepressors or histone deacetylases (HDACs), the chromatin structure closes and transcription is inhibited (Schäcke et al., 2007). The GC-induced leucine zipper (*GILZ*) gene has been identified as a downstream mediator of GC antiinflammatory and immunosuppressive effects, and may eventually be a pharmacological target (Ayroldi et al., 2014). Some of these compounds also have shown reduced tendency for insulin antagonism and therefore metabolic side effects (Brandish et al., 2014).

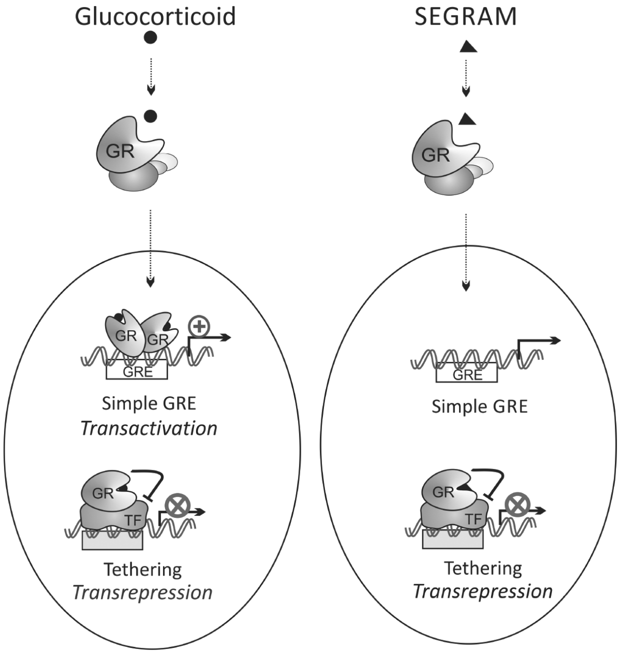

Figure 29.4 Mechanism of transrepression by glucocorticoids and selective glucocorticoid receptor agonists/modulators (SEGRAMs). Induction of lipocortin and inhibition of phospholipase A_2: An important mechanism for antiinflammatory and immunosuppressive effects of glucocorticoids is the inhibition of phospholipase A_2 (PLA_2), the enzyme responsible for the release of arachidonic acid from membranes prior to its further metabolism by the cyclooxygenase (COX) and lipoxygenase (LOX) pathways (Figure 29.5). Glucocorticoids enhance the production of a protein called *lipocortin,* which inhibits the enzyme phospholipase A_2 in the cell membrane, thereby inhibiting the formation of prostaglandins, leukotrienes, and PAF (Figure 29.5). Glucocorticoids also may inhibit other phospholipases, such as phospholipase C (Barragry, 1994; Goldfien, 1992; Sorenson et al., 1988). Lipocortin-1, a 37 kDa member of the annexin superfamily of proteins, plays a major regulatory role in systems as diverse as cell growth regulation and differentiation, neutrophil migration, CNS responses to cytokines, neuroendocrine secretion, and neurodegeneration (Flower and Rothwell, 1994).

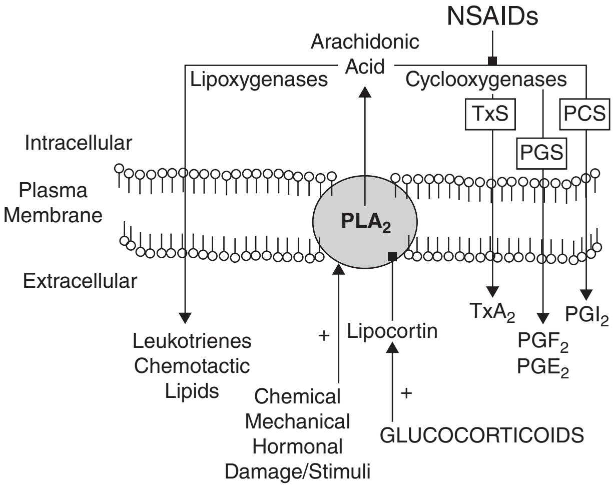

Figure 29.5 Comparison of the effects of glucocorticoids and nonsteroidal antiinflammatory drugs (NSAIDs) on arachidonic acid–derived mediators of inflammation. Glucocorticoids stimulate the production of lipocortin, which inhibits the activity of plasma phospholipase A_2 (PLA_2) and thereby inhibits the release of arachidonic acid and indirectly the production of newly formed inflammatory mediators of the cyclooxygenase pathway as well as the lipoxygenase pathway. The net result is a reduction in production of leukotrienes and chemotactic compounds, as well as less formation of thromboxane A_2 (TxA_2) by thromboxane synthase (TxS), of prostaglandins E_2 and $F_{2\alpha}$ by prostaglandin synthase (PGS), and of prostacyclin (PGI_2) by prostacyclin synthase (PCS).

Steroid receptor isoforms: Glucocorticoid and mineralocorticoid receptors (GR and MR, respectively) form a class of proteins within the nuclear receptor superfamily of receptors including glucocorticoids, mineralocorticoids, estrogens, progesterone, androgen, vitamin D, and retinoic acid. They are widely conserved throughout the species. Glucocorticoid receptors are critical for normal development and differentiation and are essential for life (Duma et al., 2006). For the human GR, there exists a steroid-binding isoform of 777 amino acids, termed α, and a nonsteroid binding β isoform of 742 amino acids, which is identical to the α isoform through the first 727 amino acids (Figure 29.6). Most effects are due to GRα for GR are multiple translation isoforms, and each may undergo different types and degrees of posttranslational modification. Initially, it was thought that GRβ was not physiologically significant but it is now known that it is constitutively expressed in the nucleus and antagonizes the activity of GRα (Ayroldi et al., 2014). GRα is considered the classical GR responsible for most genomic actions, whereas the β isoform has been implicated in the conveyance of glucocorticoid resistance, and possibly a role in autoimmune and inflammatory disorders. It has been suggested that GRβ inhibits GRα transcriptional activity by interference with formation of the coactivator complex.

Much remains to be clarified mechanistically, but it has been suggested that GRβ overexpression may either be neutral, or might lead to anti- or proinflammatory states. There would be pharmacological relevance of GRβ overexpression as an antiinflammatory or to suppress

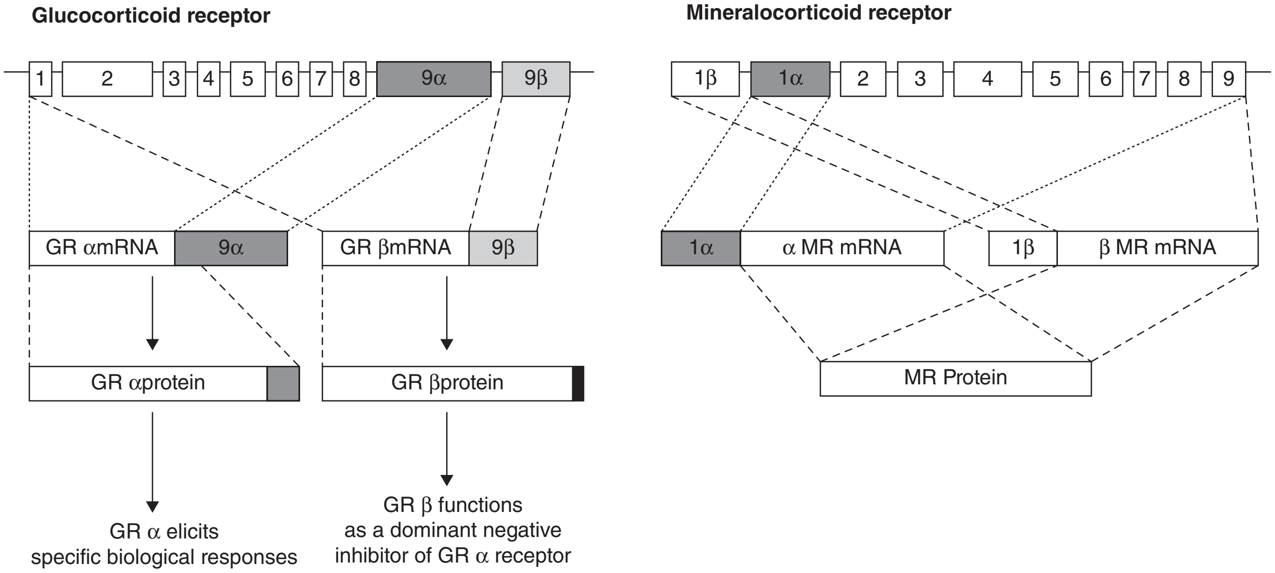

Figure 29.6 Schematic structure of the human genes encoding the glucocorticoid receptor (GR) and mineralocorticoid receptor (MR). Splice variants have been described for both receptors; in the case of the glucocorticoid receptor, there is evidence that the GR β isoform can act as a dominant negative inhibitor of GR α action. mRNA, messenger ribonucleic acid. Source: Stewart, 2003. Reproduced with permission of Elsevier.

metabolic side effects of glucocorticoids. To date, most studies report higher expression of GRβ in autoimmune, inflammatory, or glucocorticoid-resistant states. Neutrophils have a normally high β : α GR ratio, and this may account for their relative glucocorticoid-resistance. However, no study has yet evaluated the effect of acute or chronic glucocorticoid administration on GRβ expression. Nonetheless, proinflammatory cytokines induce an overexpression of GRβ and expression of this GR isoform has been postulated as a possible predictor of therapeutic failure with glucocorticoid therapy (Duma et al., 2006).

Posttranslational modifications: The function of GRs can be subsequently altered by posttranslational modifications, such as phosphorylation, ubiquitination, and SUMOylation. Ultimately, such changes may alter subcellular distribution, transcriptional activity, and protein–protein interactions. Ubiquitination is believed to be a major mechanism by which the degradation rates of GRs are regulated, regulating targeting to proteasome degradation. This is a highly conserved mechanism among eukaryotes. Addition of a small ubiquitin-related modifier-1 (SUMO-1) is called *SUMOylation* and may also impact protein stability and localization. For example, of significance to immunosuppressive or anticancer therapy, the phosphorylation state of the GR may impact glucocorticoid sensitivity during the cell cycle. Glucocorticoid treatment increases phosphorylation during the S phase, but not during the G2 or M phases. As a result, cells synchronized to the S phase were responsive to glucocorticoids, whereas those in G2/M phase were not (Duma et al., 2006).

Nongenomic Effects of Glucocorticoids

In shock and pulse immunosuppressive therapy, very high doses of glucocorticoids are administered. At such doses, cGRs are believed to be saturated (Table 29.2) and effects are unlikely to be limited to receptor-mediated phenomena. At high GC concentrations, nonspecific effects due to direct interaction with the cell membrane lipid may occur (Figure 29.3). These effects are too rapid to be regulated transcriptionally and are termed *nongenomic* but represent several possible mechanisms. Rapid GC effects might occur by interaction of GCs with specific membrane receptors. For example, a plasma-membrane form of GR has been shown in B cells and peripheral blood mononuclear cells. GCs may also act on the plasma membrane by nonspecific physicochemical mechanisms, particularly when at high concentrations. Through such mechanisms, they may inhibit Na^+ and Ca^{++} plasma membrane transport or increase H^+ leak of the mitochondria. The former mechanism in lymphocytes has been implicated as part of the rapid immunosuppression induced by glucocorticoids. The effects of GCs on ion fluxes and vascular permeability are independent of protein synthesis (Muller and Rankawitz, 1991; Reul et al., 1990). In fact, the rapid effect of GCs at inhibition of allergic conditions has been shown to be caused by a reduction in intracellular calcium (Zhou et al., 2008). Nongenomic effects of glucocorticoids have also been described on different cellular processes, such as actin polymerization, neuronal membrane conductance, and other signal transduction mechanisms. For example, short-term glucocorticoid treatment reduced antigen-induced phosphorylation of mitogen-activated protein (MAP)–extracellular signal-regulated kinase (ERK, MEK), as well as reduced phospholipase A_2 (PLA_2) (Song and Buttgereit, 2006).

Specific membrane-associated receptors for glucocorticoids may be involved in the rapid effects of these agents in shock conditions (Gametchu et al., 1991; Grote et al., 1993; Liposits and Bohn, 1993). Glucocorticoids as cholesterol-like compounds, may change membrane fluidity, thereby regulating plasma membrane $GABA_A$, EGF, insulin-like growth factor-I (IGF-I), and dopamine receptors. Receptor-mediated insertion of steroid hormones into DNA may also take place, with the steroid acting as a transcription factor. These diverse modes of action provide for integrated rapid and/or prolonged effects to address the physiological needs of the individual (Brann et al., 1995).

Glucocorticoids can induce the rapid phosphorylation and membrane translocation of annexin-1, an important antiinflammatory protein. They also have been shown to activate endothelial nitric oxide synthase (eNOS) via actions on phosphatidylinositol 3-kinase and protein kinase B, resulting in vasodilatation associated with cardio protective effects of glucocorticoids. Neuroprotection following high-dose glucocorticoids may also be associated with a nongenomic effect, again possibly by eNOS activation and increased cerebral blood flow (Song and Buttgereit, 2006).

Membrane-bound states of the cytosolic glucocorticoid and mineralocorticoid receptors have also been described. Aldosterone receptors on plasma membranes of lymphocytes and smooth muscle cells appear to trigger changes in Ca^{++}, IP3, cAMP, and protein kinase C. Supporting clinical significance, the number of plasma membrane-bound GRs correlates with the ability of GCs to induce lymphocyte death. Further work is necessary to clarify the functional role and cellular mechanisms associated with membrane-bound GR. Current thinking is that there is only one cytosolic GR, which may be either unliganded and membrane-associated, or liganded and act as a "classical" nuclear transcription factor. In future pharmaceutical development, glucocorticoids with preference for membrane-bound GRs may have enhanced immunosuppressive activity with fewer side effects (Buttgereit et al., 2004; Song and Buttgereit, 2006; Loewenberg et al., 2007).

Physiological Effects of Glucocorticoids

A principal role of glucocorticoids is the maintenance of fluid homeostasis by regulation of volume and composition of body fluids and by being permissive for essential cellular metabolism. Without glucocorticoids, an animal cannot survive a stressful incident. The glucocorticoids have widespread effects because they influence the function of most cells in the body. Glucocorticoids in physiological quantities are essential for the dilution of the renal filtrate into the hyposthenuric range. Other physiological roles of glucocorticoids are to increase gluconeogenesis, decrease protein synthesis, and increase lipolysis with the release of glycerol and free fatty acids (an insulin-antagonistic effect). Although many of the effects are dose related, glucocorticoids may also act in a permissive manner to optimize certain cellular reactions such as the gluconeogenesis stimulated by glucagon and catecholamines. The physiological effects of glucocorticoids in the fed state are not very significant; however, during fasting, glucocorticoids contribute to the maintenance of glucose concentrations by increasing the release of glucose by the liver and increasing gluconeogenesis and glycogen deposition by stimulating glycogen synthase. The effect on muscle is catabolic because glucose uptake decreases and amino acid release (gluconeogenesis) increases.

Glucocorticoids stimulate adipocyte differentiation, promoting adipogenesis through activation of key adipocyte differentiation genes such as those coding for lipoprotein lipase, glycerol-3-phosphate dehydrogenase, and leptin. Glucocorticoids also are permissive for activity of the hormone-sensitive lipase (HSL), which is responsible for mobilization of free fatty acids from adipose stores. Lipolysis is stimulated, therefore, when insulin is lacking or being greatly antagonized; ketogenesis may result (Aron and Tyrrell, 1994; Ferguson, 1985a; Goldfien, 1992; Haynes, 1990; Melby, 1974; Wilcke and Davis, 1982).

Glucocorticoids also maintain microcirculation, normal vascular permeability, and stability of lysosomal membranes, and suppress inflammatory reactions, although these functions are more commonly associated with the pharmacological effects of glucocorticoids (Aron and Tyrrell, 1994; Tyrrell et al., 1994).

Pharmacological Effects

Growth and Development

Glucocorticoids play a physiological role in the development of pulmonary surfactant in the near-term fetus, allowing an adaptation to air breathing. GCs stimulate lung maturation through the synthesis of surfactant proteins. GR knockout mice do not survive because of lung atelectasis. Prematurity with delayed development of the adrenal axis in foals has been suspected as a cause of neonatal respiratory distress syndrome. Although glucocorticoids stimulate growth hormone (GH) gene transcription in physiological quantities, glucocorticoids in excess inhibit linear skeletal growth, via catabolic effects on connective tissue and muscle and inhibition of IFG-1 effects. GCs also stimulate the adrenal medullary enzyme converting norepinephrine to epinephrine (Aron and Tyrrell, 1994; Tyrrell et al., 1994; Stewart, 2003).

Energy Metabolism

Glucocorticoids have an antagonistic effect to that of insulin, leading to increased glucose production from amino acids (gluconeogenesis) and reduced incorporation of amino acids into protein. As stated above, glucocorticoids enhance lipolysis; however, glucocorticoid excess (pharmacological amounts) or spontaneous hyperadrenocorticism may result in redistribution of fat because glucocorticoids stimulate appetite, thereby stimulating hyperinsulinemia, which results in lipogenesis. As a result, diabetes mellitus may result from prolonged glucocorticoid use at high dosages in animals with diminished insulin secretory capacity (prediabetics). Muscle wasting and weakness are not uncommon with glucocorticoid excess; although glucocorticoids stimulate protein and RNA synthesis in the liver, they have catabolic effects in lymphoid and connective tissue, muscle, fat, and skin. While not usually a recognizable clinical problem in domestic animals, osteoporosis may result in people with Cushing's syndrome or on chronic glucocorticoid administration. The problem likely is most significant in areas of healing bone; glucocorticoids directly inhibit bone formation by inhibiting osteoblast proliferation and the synthesis of bone matrix while stimulating osteoclast activity. In addition, glucocorticoids potentiate the action of parathyroid hormone (PTH) and 1,24-dihydroxycholecalciferol ($1,25(OH)_2$-D_3) and inhibit the gut absorption of calcium, an effect that can be used to advantage in hypercalcemic states. However, in the young animal, the catabolic effects of excessive amounts of glucocorticoid reduce growth. In children, this reduced growth is not prevented by growth hormone (Aron and Tyrrell, 1994; Tyrrell et al., 1994). In adult dogs, 2 mg/kg prednisone for 30 days reduced bone mineral density by 14% as measured by helical computer tomography (Costa et al., 2010).

Water and Electrolyte Balance

Glucocorticoid use invariably leads to polyuria and polydipsia via inhibition of ADH release and action, as well as alteration of the animal's psyche, resulting in increased water intake. No glucocorticoid given in large doses is completely devoid of mineralocorticoid (salt-retaining and K^+-losing) activity; therefore, excessive use may precipitate or exacerbate hypertension and induce hypokalemia. In part by increasing extracellular fluid volume, glucocorticoids increase the glomerular filtration rate and are required in physiological amounts for maximal dilution of urine (Ferguson, 1985a; Melby, 1974; Nakamoto et al., 1992; Smets et al., 2012).

Immune and Hematological Effects

Often the desired result of a therapeutic application, antiinflammatory effects of glucocorticoids are primarily seen at pharmacological doses. Glucocorticoids result in alterations in the concentration, distribution, and function of peripheral leukocytes and in inhibition of phospholipase A_2 activity in the plasma membranes of these cells. Glucocorticoids act indirectly by inducing lipocortin synthesis, which in turn inhibits arachidonic acid release from membrane-bound stores, and also by inducing transforming growth factor-β (TGF-β) expression, which subsequently blocks cytokine synthesis and T-cell activation. In addition to contributing to maintenance of the microcirculation and cell membrane integrity, glucocorticoids interfere with progressive dissolution and disruption of connective tissue and cells, possibly by stabilizing lysosomal membranes (Aron and Tyrrell, 1994; Aucoin, 1982; Barragry, 1994). Although lysosomal stabilization by glucocorticoids has been demonstrated experimentally, it is hard to know what benefit these effects have in clinical situations. Glucocorticoids also decrease formation of induced histamine (histamine produced locally by cells during injury), the action of which is not effectively blocked by standard doses of antihistamines. They also antagonize toxins and kinins, reducing the resultant inflammation. It is important to realize, however, that most of their effects are *nonspecific;* that is, they have profound metabolic effects regardless of the initial insult.

Glucocorticoids are used to advantage to suppress both the number of cells and the actions of the immune system. The suppressive effects on cell-mediated immunity predominate over those on humoral immunity. Antibody production is generally unaffected by moderate dosages of glucocorticoids and is inhibited only at high dosages and with long-term therapy. They cause lymphopenia and eosinopenia, an effect secondary to cell redistribution and/or lysis, and lead to increased vascular demargination of neutrophils from the vascular bed to lymphoid tissue. Glucocorticoids inhibit virus-induced interferon synthesis and diminish the functional capacity of monocytes, macrophages, and eosinophils through inhibition of the formation of ILs such as IL-1 (macrophages), IL-2 (lymphocytes), IL-3, and IL-6 and other chemotactic factors. Glucocorticoids can induce apoptosis on normal lymphoid cells and play a key role in the physiology of thymic selection. They inhibit monocyte differentiation into macrophages and macrophage phagocytosis and cytotoxic activity (Barragry, 1994; Ehrich et al., 1992; McDonald and Langston, 1994; Melby, 1974; Tyrrell et al., 1994; Buttgereit et al., 2004).

In recent years, greater understanding of the mechanisms of GC inhibition of cell-mediated immunity has developed, and the GC-induced leucine zipper (*GILZ*) gene has emerged as a critical mediator. In response to GCs, GILZ up-regulates and inhibits T cells through inhibition of anti-CD3-induced activation and apoptosis. GILZ also interacts with and inhibits NF-κB. Other GILZ targets have been identified, including AP-1, Raf-1, and Ras, and each has been implicated in the effects of GCs. GILZ silencing diminishes the antiproliferative activity of dexamethasone and reduces inhibition of cytokine-induced COX-2 expression (Ayroldi and Riccardi, 2009; Ayroldi et al., 2014). In addition to the GILZ-mediated effects, GCs appear to up-regulate repair-phase cytokines like TGF-β and platelet-derived growth factor (PDGF), possibly explaining the suppressive effect on healing and fibrosis (Pallardy and Biola, 1998; Buttgereit et al., 2004).

In the clinical setting, GCs are used for their ability to induce apoptosis of malignant lymphoid cells. The mechanisms of apoptosis induced by glucocorticoids fall roughly in two categories, depending on the type of lymphocytes: induction of "death genes" such as IκB and *c-jun* or repression of survival factors such as AP-1 and *c-myc.* By inhibiting the production of Th1 cytokines, glucocorticoids may enhance Th2 cell activity and generate a long-lasting state of tolerance.

Cardiorespiratory Effects

In addition to indirect effects on electrolyte metabolism, glucocorticoids have direct positive chronotropic and inotropic actions on the heart. They appear to block the increased permeability of capillaries induced by acute inflammation, reducing transport of protein into damaged areas and maintaining microcirculation. Because glucocorticoids are necessary for maximal catecholamine sensitivity, they contribute to maintenance of vascular tone (Ferguson et al., 1978; Nakamoto et al., 1992). In shock, production of vasoactive products of lipid peroxidation (arachidonic acid cascade), such as the vasoconstrictor thromboxane A_2, may be decreased by glucocorticoids, but probably only in the early stage of cell disruption. Glucocorticoids cause vasoconstriction when applied directly to vessels. They decrease capillary permeability by inhibiting the activity of kinins and bacterial endotoxins and by reducing the amount of histamine released by basophils.

Glucocorticoids may induce hypertension in animals and humans through the following mechanisms: (i) activation of the renin–angiotensin system due to an increase in plasma renin substrate; (ii) reduced activity of the hypotensive kallikrein–kinin system, prostaglandins (PGs), and the endothelium-derived relaxing factor, nitric oxide (NO); and (iii) increased pressor responses to angiotensin II and norepinephrine. Furthermore, the number of angiotensin II type 1 receptors of vascular smooth muscle cells is significantly increased by glucocorticoids (Saruta, 1996).

Glucocorticoids increase the number and affinity of β-adrenergic receptors. Glucocorticoids prevent receptor down-regulation and therefore tachyphylaxis, resulting in potentiation of the effects of β-adrenergic agonists on bronchial smooth muscle, an important effect in the asthmatic patient (Sprung et al., 1984; Tyrrell et al., 1994; Wilcke and Davis, 1982).

CNS Effects

Although rarely described in domestic animals, glucocorticoids (or lack of them) have marked effects on the psyche, resulting in a form of mental, as well as physical, dependence (Ferguson, 1985a; Metz et al., 1982). It is known that pretreatment of neonatal rats with dexamethasone provides protection against hypoxic–ischemic brain damage. This effect is likely mediated via glucocorticoid receptors, because glucocorticoid receptor antagonist RU38486 reverses the benefit. The neuroprotection also appears to be related to alterations in cerebral metabolism. Glucose utilization is reduced prior to hypoxia–ischemia and is better maintained following dexamethasone. High-energy phosphates in the brain are higher in dexamethasone-treated animals. Thus, glucocorticoids may provide their protection against hypoxic–ischemic damage by decreasing basal metabolic energy requirements and/or increasing the availability or efficiency of use of energy substrates (Tuor, 1997).

Endocrine Effects

Glucocorticoids, in addition to being diabetogenic, also have marked effects on hypothalamic and pituitary function. ACTH, β-lipotropin, thyroid-stimulating hormone (TSH), follicle-stimulating hormone (FSH), and growth hormone (GH) synthesis and secretion are all suppressed; however, β-endorphin levels are unaffected. Glucocorticoids, even at "physiological" dosages (0.22 mg/kg prednisolone once daily orally in the dog), result in HPAA suppression, as indicated by reduction in the ACTH-stimulated cortisol concentration increment and by reduction of the ratio of the zona fasciculata and reticularis to zona glomerulosa in the adrenal gland. Antiinflammatory dosages of prednisolone (0.5 mg/kg q 12 h orally) resulted in adrenal suppression within 2 weeks of therapy (Chastain and Graham, 1979). In another study in dogs, 1 month of the same dosage of prednisolone orally resulted in profound suppression of endogenous plasma ACTH and cortisol concentrations, CRH-stimulated ACTH release, and ACTH-stimulated cortisol release. However, following withdrawal of the prednisolone, the HPAA returned to normal within 2 weeks (Moore and Hoenig, 1992). A similar ability to recover from exogenous glucocorticoids was seen in the cat. A dosage of 2 mg/kg q 12 h of methylprednisolone given orally for 7 days resulted in suppression of ACTH-stimulated cortisol and CRH-stimulated ACTH, but these changes completely reversed by 7 days after withdrawal of the exogenous glucocorticoid (Crager et al., 1994). Higher dosages and long-acting preparations (dexamethasone, triamcinolone, depot products) may result in more pronounced HPAA suppression (Kemppainen and Sartin, 1984; Kemppainen, 1986; Kemppainen et al., 1982). Even hydrocortisone at 10 mg/kg twice a day for 4 months led to ultrasonographically evident adrenal atrophy that was reversible after 1 month of withdrawal (Pey et al., 2012).

The effect of glucocorticoids on glucose metabolism is time and dose dependent; insulin and glucose concentrations, or glucose tolerance, were not significantly altered by the administration for 28 days of an antiinflammatory dosage of oral prednisone (Moore and Hoenig, 1993). However, daily administration of high dosages of dexamethasone and growth hormone is a reliable model for induction of diabetes mellitus in the cat (Hoenig et al., 2000). There also have been case reports of diabetes mellitus induced in dogs after administration of corticosteroids and methylprednisolone pulse therapy (Jeffers et al., 1991).

Pharmacological doses of glucocorticoids generally reduce serum thyroid hormone concentrations, presumably through suppression of pituitary TSH. These effects have been well documented in the dog, are not as significant in the cat, and are not well studied in other domestic species (Ferguson and Peterson, 1992; Kaptein et al., 1992; Moore et al., 1993). The metabolic consequences of these lowered concentrations of thyroid hormones are not known in the dog; however, a state of hypothyroidism is not believed to be the result (Jennings and Ferguson, 1984).

Gastrointestinal Effects

Physiological glucocorticoid responses contribute to the maintenance of the gastric mucosal integrity following ulcerogenic stimuli. The role of glucocorticoids in gastroprotection becomes especially important where there is deficiency of PGs or NO or desensitization of intestinal sensory neurons (CSN). In rats with normal corticosterone, these insults do not result in gastric mucosal disruption, but do in adrenalectomized rats (Filaretova et al., 2007). These findings may explain the observation of bloody diarrhea in dogs with glucocorticoid deficiency and/or Addison's disease.

However, pharmacological doses of glucocorticoids stimulate excessive production of acid and pepsin in the stomach and may cause peptic ulcer. In an experimental canine fundic pouch model of acid secretion, the effect of prednisolone (2 mg/kg per day given parenterally for three doses, 2 weeks or 12 weeks) on gastric mucosal H^+ permeability was studied. Acute administration (<2 weeks) had no effect. Chronic administration (12 weeks) increased slightly the basal H^+ secretion rate, and increased mucosal permeability by 50% when simultaneously administered with aspirin (Chung et al., 1978). Similarly, 0.25 mg/kg SC q 12 h for 3 days induced endoscopically evident gastric lesions in dogs (Boston et al., 2003). Glucocorticoid lesions are exacerbated by simultaneous administration of nonsteroidal antiinflammatory drugs (NSAIDs) (Dow et al., 1990; Narita et al., 2007). In rats, dexamethasone-induced ulceration has led to alterations in the phospholipid fatty acid profile (increased linoleic acid and decrease in other polyunsaturated fatty acids, PUFAs). PUFA supplementation or the administration of an H_2 receptor antagonist reduced ulcerization with near normalization of changes in the phospholipid fatty acid profile (Manjari and Das, 2000).

Prednisolone and dexamethasone, studied in canine colon cell culture, had no effect on the intestinal cell tight junction barrier function, but did prevent the increase in permeability induced by TNF-α. Specifically, glucocorticoids, acting through nuclear receptors, inhibited the TNF-α–induced increase in myosin light chain kinase protein expression, which was shown to mediate increased intestinal tight junction permeability (Boivin et al., 2007).

Glucocorticoids facilitate fat absorption and appear to antagonize the effect of vitamin D on calcium absorption. Therefore, glucocorticoids are employed in chronic hypercalcemic states in an attempt to inhibit gastrointestinal calcium absorption (Aron and Tyrrell, 1994; Tyrrell et al., 1994). Glucocorticoid therapy may cause calcinosis cutis in dogs, but no specific dose or set of factors has been identified to consistently cause it (Doerr et al., 2013).

Chemistry

Source

Although the natural corticosteroids can be obtained from animal adrenal glands, they are usually synthesized from cholic acid or steroid sapogenins found in plants of the Liliaceae and Dioscoreaceae families. Further modifications of these steroids have led to the marketing of a large group of synthetic steroids with special characteristics that are pharmacologically and therapeutically important (Table 29.3 and Figures 29.7 and 29.8).

Structure–Activity Relationships

The actions of the synthetic steroids are similar to those of cortisol (see Section Pharmacological Effects). They bind to the specific intracellular receptor proteins and produce the same effects but have different ratios of glucocorticoid-to-mineralocorticoid potency (see Table 29.3).

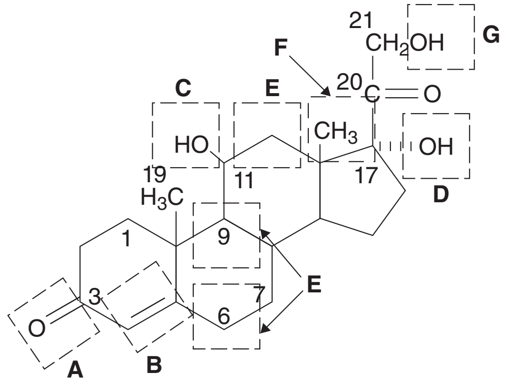
Table 29.3 Characteristics of various glucocorticoid bases

	Potency			
Drug	**Glucocorticoid**[a]	**Mineralocorticoid**	**HPAA suppression**	**Alternate-day therapy possible?**
Short-acting (duration of action: <24 hours)				
Hydrocortisone	1	++	+	No (too short)
Cortisone	0.8	++	+	Yes (not ideal)
Prednisone	4	+	+	Yes
Prednisolone	4	+	+	Yes
Methylprednisolone	5	+	+	Yes
Intermediate-acting (duration of action: 24–48 hours)				
Triamcinolone	5	0	++	No
Long-acting (duration of action: <48 hours)				
Flumethasone	15	0	+++	No
Dexamethasone	30	0	+++	No
Betamethasone	30	0	+++	No

Effective antiinflammatory time equals the HPAA suppression time in most cases. However, the therapeutic success and fewer side effects with alternate-day therapy stem from the fact that some preparations have slightly longer antiinflammatory or immunosuppressive action than their action to suppress the HPAA.

[a] Compared with hydrocortisone on a mg-for-mg basis.

HPAA, hypothalamic–pituitary–adrenal axis.



Cortisol

Figure 29.7 Structure–activity relationships of glucocorticoids. Shown on the structure of the compound cortisol are the important structural sites determining the activity of a glucocorticoid base. *A:* 3 keto group essential for glucocorticoid activity; *B:* 4,5 double bond essential for glucocorticoid activity; *C:* 11 hydroxyl essential for optimal glucocorticoid activity; *D:* 17 α hydroxyl is important for glucocorticoid activity; *E:* 16 methylation or fluorination reduces mineralocorticoid activity considerably and increases glucocorticoid activity; *F:* 20 keto group is important for glucocorticoid activity; *G:* 21 hydroxyl is essential for mineralocorticoid activity and is the site of esterification.

Steroid Base

Figures 29.7 and 29.8 show the steroid base, or carbon skeleton, of glucocorticoids. The structure of the base determines the *antiinflammatory (glucocorticoid) potency, mineralocorticoid potency,* and the *duration of action* once at the site of action.

Alterations in the steroid base structure influence its affinity for glucocorticoid and mineralocorticoid receptors, as well as its protein-binding avidity, side-chain stability, rate of reduction, and metabolic products. Certain structures on the steroid base are essential for glucocorticoid activity (Figures 29.7 and 29.8). An 11-ketol is essential for glucocorticoid activity, and compounds like cortisone and prednisone must first be reduced in the liver from the 11-carbon ketone to the ketol before full activity is seen. The 1,2 double bond provides a fourfold increase in glucocorticoid activity. The C-3 and C-20 ketone groups are also essential for glucocorticoid activity. The addition of 16-α-methyl 9-α-fluoro groups results in compounds with enhanced antiinflammatory activity. Further substitution at the 17 ester position results in a new group of extremely potent steroids (e.g., beclomethasone and betamethasone) that are effective when applied topically for skin diseases and by inhalation for treating asthma. Modifications of the glucocorticoid molecular structure also alter the tendency for the molecule to bind with CBG in the plasma. An increase in binding to CBG results in a lower tendency for the hormone to be metabolized. Halogenation at the 9 position, unsaturation of the 1,2 bond, and methylation at the 2 or 16 position will prolong the half-life by more than 50–70%. The 11-hydroxyl group also appears to inhibit destruction, since the half-life of 11-deoxycortisol is half that of cortisol. In some cases, the agent administered is a prodrug; prednisone is rapidly reduced to prednisolone, and cortisone is rapidly converted to cortisol by the liver. The synthetic corticosteroids for oral use are in most

cases rapidly and completely absorbed when given by mouth.

Ester

Esterification of the alcohol at C-21 serves a number of potential purposes. The ester moiety determines to a significant extent the water/lipid solubility ratio and also influences the duration of action of the base compound's release from subcutaneous or intramuscular sites. Tissue esterases cleave the ester, resulting in free base, which then is distributed via the circulation to tissue sites of action. Routes of administration and duration of release are given for the following esters:

1) phosphate and hemisuccinate: IV or IM, rapid action and metabolism;
2) acetate, diacetate, tebutate: subcutaneous or IM depots, 2–14 days;
3) acetonide: subcutaneous or IM depots, poorly H_2O soluble;
4) pivalate: subcutaneous or IM depots; weeks to months.

The ability of a formulation to suppress the HPAA is determined by the *dosage,* the *potency of the base,* and the *duration of action of the formulation* (base + ester).

Toxicity

The main limiting factors for glucocorticoid administration are the global toxic effects of these agents. Table 29.4 lists most of the reported side effects as described in the dog, the species in which glucocorticoids are most widely used. Of course, there is variability from species to species. The following discussion highlights the basis for some of these effects.

Metabolic/Endocrine Effects

The endocrine manifestations of glucocorticoid administration can be severe. Iatrogenic Cushing's syndrome may develop with adrenal insufficiency on withdrawal of the medication. The gluconeogenic effects may unmask or exacerbate diabetes, and polyuric and polydipsic states and may induce hypertension.

CNS Effects

In animals, the effects on mental status are difficult to assess or compare with those in humans; however, glucocorticoids likely induce a state of well being. Neurologically, there is also evidence that glucocorticoids may decrease the threshold for seizures. Lethargy and panting occasionally develop in dogs and cats. Rapid withdrawal of glucocorticoids can induce depression and irritability (Ferguson, 1985a, 1985b; McDonald and Langston, 1994).

Blood and blood chemistry
Increases in:
  Neutrophils
  Erythrocytes
  Monocytes
  Platelets
  Alkaline phosphatase[a]
  Cholesterol
  Glucose
  Alanine aminotransferase
Decreases in:
  Eosinophils[a]
  Lymphocytes
  Blood urea nitrogen

Central nervous system
Behavioral and mood changes (depression, increased irritability)
Lethargy
Panting

Endocrine
Iatrogenic Cushing's disease, HPAA suppression[a], secondary adrenocortical insufficiency
Reduced thyroid hormone (T_4 and T_3) levels
Reduced gonadotropin and sex steroid levels
Anestrus, testicular atrophy, reduced libido
Elevated insulin levels, carbohydrate intolerance
Reduced vitamin D levels
Elevated parathyroid hormone levels

Gastrointestinal
Polyphagia
Anorexia (rare)
Diarrhea (may be bloody)
Increased gastric acid secretion
Hepatomegaly
Hepatopathy
Pancreatitis
Colonic perforation

Renal
Polyuria with secondary polydipsia[a]
Increased urinary calcium excretion

Musculoskeletal
Muscle atrophy
Weakness, exercise intolerance
Myotonia (rare)
Osteoporosis

Skin
Calcinosis cutis
Thin skin
Bilateral hair loss
Increased bruising

Other
Increased risk of infection
Enhanced spread of infection
Poor wound healing
Redistribution of body fat
Reduced growth

[a] Relatively common finding in dogs.
HPAA, hypothalamic–pituitary–adrenal axis; T_3, triiodothyronine; T_4, thyroxine.

Lending to the understanding of their potential protective effects at high doses in central nervous system injury, glucocorticoids have been shown to protect neurons from apoptosis by a mechanism involving the cyclin-dependent kinase inhibitor $p21_{Waf1/cip1}$, an effect reversed by receptor antagonists as well as inhibitors of PI3- and Akt-kinase (Harms et al., 2007).

Gastrointestinal and Hepatic Effects

The gastrointestinal and hepatic effects of glucocorticoids are among the most limiting regarding chronic administration. Glucocorticoids clearly induce a form of micronodular cirrhosis and stimulate the steroid-specific isozyme of alkaline phosphatase. In addition to hepatopathy and hepatomegaly, glucocorticoid excess may result in increased gastric acid and gastric ulceration, but more commonly high doses of potent glucocorticoids cause colonic perforation in dogs. Of course, glucocorticoids may stimulate appetite, an effect occasionally used to advantage in some therapeutic situations. Rarely, the animal will respond with anorexia. It has been postulated that glucocorticoids may also cause pancreatitis.

Musculoskeletal Effects

Chronic glucocorticoid administration induces excessive catabolism and muscle atrophy. Animals may become clinically weak and be unable to exercise optimally. Bone growth may be inhibited and antagonism of vitamin D activity may result in osteoporosis with chronic administration of glucocorticoids.

Dermatological Effects

Glucocorticoids reduce collagen synthesis and thereby reduce the rate of wound healing. The skin becomes thin and more easily stretched and bruised due to increased capillary fragility. Dogs on large dosages of glucocorticoids often develop bilateral symmetrical alopecia, known as a "cushingoid" appearance. Cats tend to be less susceptible to these effects. Occasionally, exogenous glucocorticoid administration will induce calcium deposition in the dystrophic epidermis; however, the incidence in dogs appears to be less than with spontaneous hyperadrenocorticism (Scott, 1982).

Immunological Effects

Although immune suppression is often the desired therapeutic effect of glucocorticoids, these agents are notorious for exacerbation of clinical or latent infectious disease processes. Animals on chronic glucocorticoid therapy have a higher incidence of bacterial infections; in one study, 75% of dogs on glucocorticoids for allergic skin disease had clinical or subclinical urinary tract infections. Of course, by inhibiting the cell-mediated immune response to an infection, glucocorticoids slow the function of immune cells that help contain an infection (Aucoin, 1982; Fauci, 1976; Ferguson, 1985a, 1985b; Siegel, 1985).

Reproductive Effects

High doses of glucocorticoids induce parturition during the latter part of pregnancy in ruminants and horses (Barragry, 1994). There is also now evidence that dexamethasone can cause abortion in the dog. Glucocorticoids generally have teratogenic effects during early pregnancy and should be avoided in the breeding animal if possible.

Severe Sequelae

Glucocorticoid overdosage may lead to severe and potentially fatal toxicity associated with sepsis resulting from GI tract disruption and immune suppression in the dog (Bellah et al., 1989). Although pituitary pars intermedia dysfunction and hypercortisolemia have been associated with an increased incidence of laminitis in horses, a review has suggested that glucocorticoid-induced laminitis is relatively rare (Cornelisse and Robinson, 2013). Glucocorticoids appear to potentiate the action of catecholamines in the equine digit. Because this constriction is more pronounced on venous beds than on arteriolar beds, the net result is often digital congestion and edema (Barragry, 1994). The enzyme 11-β steroid dehydrogenase type 1 (11-β HSD1) is occasionally elevated in hoof lamellar tissues during conditions of glucocorticoid excess, resulting in a greater tendency toward metabolically active glucocorticoids. Glucocorticoids have been postulated to reduce digit perfusion by a direct action on smooth muscle as well as by inducing insulin resistance. Endothelial damage associated with elevated glucose leads to increased production of endothelin-1 and a reduction in nitric oxide (NO) production tending to promote vasoconstriction (Johnson et al., 2004).

Principles of Rational Glucocorticoid Therapy

Because of their wide ranging and nonspecific effects, reports of the clinical use of glucocorticoids are replete with pragmatic recommendations regarding dosage, duration of therapy, and severity of side effects. Much has been adopted from clinical use in humans, and much more is known about the fine points of glucocorticoid therapy in dogs and cats than in other species. In the following discussion, most of the specific comments will apply to the use of glucocorticoids in the dog; however, when available, appropriate information for other species will be mentioned. It is important to recognize that glucocorticoids rarely cure disease. With the possible exception of spontaneous glucocorticoid deficiency, they are used to try to suppress clinical signs long enough for a condition to run its natural course (Fauci, 1976; Ferguson, 1985a, 1985b; Melby, 1974; Wilcke and Davis, 1982).

A well-known endocrinologist named Thorn proposed, in 1966, that physicians ask themselves the following questions *before* using glucocorticoid therapy (Hench, 1952). A similar approach is proposed for use in animals:

1) How serious is the underlying disorder?
2) How long will therapy be required?
3) Is the patient predisposed to any complications of glucocorticoid therapy?
4) What is the anticipated glucocorticoid dosage?
5) Which glucocorticoid preparation should be used?
6) Have other types of treatment been used to minimize glucocorticoid dosage and side effects?
7) Is an alternate-day regimen indicated?

These questions may help develop guidelines for practical and rational glucocorticoid therapy.

How Serious Is the Underlying Disorder? How Long Will Therapy Be Required?

The following general principles should be considered when glucocorticoid therapy is employed:

Diagnose the disease first, if possible. Glucocorticoids are generally only palliative and do not provide a true cure for any disease. In addition, if used before all reasonable diagnostic tests have been completed, they may mask signs of underlying disease and complicate specific diagnosis and therapy. Though a definitive diagnosis is not always possible, a presumptive diagnosis should be proposed (Ferguson, 1985a, 1985b).

Classify the disorder into one of the following categories of glucocorticoid therapy, according to a definitive or presumptive diagnosis: physiological replacement, intensive short-term, antiinflammatory and antiallergic, immunosuppressive, and chronic palliative. Each of these usage classifications will be discussed in more detail. By using these classifications, the clinician clearly defines the goal of therapy and can choose a starting dose and formulation appropriate for the disorder.

Use glucocorticoids to accomplish specific objectives. It is important to decide on the therapeutic endpoint *before* therapy is started in order to objectively assess efficacy and determine the smallest effective dose. For example, in treatment of a dog with autoimmune hemolytic anemia, the goal for initial glucocorticoid therapy might be to raise the hematocrit from 10% to 25%. In a horse with chronic obstructive pulmonary disease (“heaves”), the goal might be to suppress the allergic reaction for 1–2 weeks in order to allow the owners to change the feeding regimen to eliminate the offending allergen. By defining a therapeutic objective, the clinician can then judge the efficacy of a treatment protocol and decide when the glucocorticoid dose should be altered or alternative therapy chosen.

The length of therapy should also be anticipated. For example, immunosuppressive therapy generally requires several months of glucocorticoid use. Accordingly, a plan for instituting and later decreasing the dose should be considered from the outset. In such a case, intermittent or alternate-day therapy would not be appropriate, and an intermediate- or long-acting glucocorticoid could be used.

Is the Patient Predisposed to Any Complications of Glucocorticoid Therapy?

Because many of the therapeutic effects of glucocorticoids are nonspecific, clinicians should anticipate the impact on the patient of the previously outlined complications of glucocorticoid use. In doing so, the risk/benefit ratio of using these potent agents is considered.

What Is the Anticipated Glucocorticoid Dosage? Which Glucocorticoid Preparation Should Be Used?

It is important to understand the relative potency and, perhaps more important, the relative *duration of action* of a glucocorticoid preparation, because the duration of antiinflammatory effects usually parallels the duration of effects on the HPAA. Success with alternate-day therapy, more commonly applied in small-animal practice, depends on selecting a glucocorticoid preparation with slightly longer antiinflammatory or immunosuppressive (beneficial) actions than HPAA-suppressive effects. *Dosages of glucocorticoids are derived by trial and error and should be constantly reevaluated.* Due to the aforementioned hazards of long-term daily glucocorticoid use, intermittent or alternate-day therapy is preferred when long-term use is necessary. As shown in Table 29.3, short- or intermediate-acting formulations, generally given orally, are most appropriate and safe for long-term use and alternate-day therapy. The goal of rational therapy is to maintain a condition in remission at the lowest effective glucocorticoid dosage (Fauci, 1976; Feldman and Nelson, 2004; Ferguson, 1985a, 1985b; Wilcke and Davis, 1982).

Classes of Glucocorticoid Usage

Physiological Replacement Therapy

Replacement therapy involves use of glucocorticoids in amounts similar to those of the naturally occurring glucocorticoids (cortisol in virtually all domestic species) from the adrenal gland. Ideal replacement therapy should mimic the adrenal gland’s hormonal output under basal conditions, with doses increasing if the animal is stressed by illness or surgery. Practically, this ideal is never achieved; however, the following regimens have been used successfully in adrenalectomized and addisonian dogs and cats. As a general rule, animals produce approximately 1 mg/kg of cortisol (hydrocortisone) every day.

It is not rational to employ alternate-day or intermittent glucocorticoid replacement therapy in a glucocorticoid-deficient animal, because the animal's metabolic well being depends upon the presence of glucocorticoids *every day.* Therefore, physiological replacement therapy is aimed at providing a small daily amount of glucocorticoid. Physiological replacement therapy is rarely indicated or applied in large animals. In small animals, hydrocortisone or cortisone at 0.2–1 mg/kg/day or, more commonly, equipotent amounts of prednisolone or prednisone at 0.1–0.2 mg/kg/day once daily orally are indicated. Unlike in man, dogs and cats do not appear to have diurnal variation in cortisol concentrations (Kemppainen, 1986). Therefore, the timing of the single daily dosage would not appear to be critical, other than that it be provided approximately the same time each day. Because stress results in higher adrenal output of glucocorticoids, this pattern should be mimicked; in general, in moderate stress, give 2–5 times the physiological dosage, and in severe stress (e.g., surgery), administer 5–20 times this dosage until the stressful experience has ended (Ferguson, 1985a, 1985b).

Intensive Short-Term and Shock Therapy

The effects of glucocorticoids in all forms of shock are still controversial; however, some evidence suggests that early treatment (probably about 4 hours postinduction in dogs) may lead to increased survival, particularly in hemorrhagic and septic shock. The nature of the formulation (particularly the ester) may affect the speed of cellular entry of glucocorticoids during shock; however, other conclusions have also been reached (Ferguson, 1985a, 1985b; Ferguson et al., 1978; Sprung et al., 1984; Wilcke and Davis, 1982; Wilson, 1979).

Glucocorticoids improve hemodynamics and enhance survival in canine models of endotoxic and hemorrhagic shock. However, therapy for shock should also include aggressive fluid therapy. Septic (endotoxic) shock is the most responsive form to glucocorticoid therapy; however, although human trials have shown improved short-term survival, most patients succumbed to chronic septicemia later (Sprung et al., 1984). Suspected endotoxic shock should be treated with fluid therapy and a broad-spectrum antimicrobial, with or without glucocorticoids. Glucocorticoids and antibiotics were synergistic when given within 2 hours of induction of septic shock in baboons.

The potential detrimental effects of massive doses of glucocorticoids should always be considered. However, proponents of glucocorticoid therapy for shock point out that short-term (~48 hour) glucocorticoid therapy has few negative effects, and the positive effects far outweigh the risks. Most human patients with sepsis survive beyond the acute stages of endotoxemia but succumb later to chronic septicemia (Sprung et al., 1984). Certainly, the immunosuppressive effects of glucocorticoids make their use contraindicated during chronic sepsis, and those supporting glucocorticoid use in septic shock do not generally advocate use other than during the early acute hypotensive state. Opponents to glucocorticoid use generally are not convinced that experimental studies in anesthetized animals adequately duplicate clinical situations and do not believe even short-term treatment to be innocuous, because of immunosuppressive effects (Wilcke and Davis, 1982).

Antiinflammatory and Antiallergic Therapy

A large proportion of glucocorticoid use in veterinary practice is designed to combat inflammation or allergy. Unfortunately, many such diseases are difficult to definitively diagnose. Therefore, misuse of glucocorticoids is not uncommon in this category. Examples of antiinflammatory and antiallergic use of glucocorticoids include symptomatic treatment of pruritic dermatoses, allergic pulmonary disease, and allergic gastroenteritis. Guidelines for antiinflammatory and antiallergic dosages vary from species to species. Prednisolone or prednisone is most commonly used in small animals at 0.55 mg/kg q 12 h given orally for induction, and then at 0.55–2.2 mg/kg every other day for maintenance. Although all dosages should be adjusted according to effect, a general, but undocumented, observation has been that cats require approximately twice the glucocorticoid dosage that dogs require to manage a similar condition. Methylprednisolone acetate may also be administered subcutaneously or intramuscularly at 1.1 mg/kg every 1–3 weeks; however, use of depot products brings the distinct disadvantage that the drug dosage cannot be stopped or reduced. Other long-acting injectable products and their duration include prednisolone acetate, 1–2 days; dexamethasone in propylene glycol, 1–7 days; triamcinolone acetonide, 3–7 days; and betamethasone valerate, 7–60 days. For practical reasons of cost and potency, dexamethasone is the most commonly used glucocorticoid in large animals.

Immunosuppressive Therapy

Protracted glucocorticoid use generally is required for immunosuppression. Therefore, use of a glucocorticoid with well-documented side effects and efficacy is recommended. It is important to use the highest recommended dosage until clinical signs abate. After that point, the dosage may be decreased in increments. In general, in small animals, the dosage may be decreased until the equivalent prednisolone dosage of 1.1 mg/kg is being given on alternate days (Aucoin, 1982; Ferguson, 1985a, 1985b). Long-term side effects of alternate-day therapy are few, and the dosage rarely must be decreased further. Therapy should not be discontinued until the autoimmune disease is in remission for 2–3 months; otherwise, signs are likely to recur (Aucoin, 1982; Fauci, 1978; Ferguson, 1985a, 1985b).

Glucocorticoids provide very nonspecific protective benefits: "The hormone appears not to extinguish the fire or to act like a carpenter to repair the damage of the fire. Instead, it appears to 'dampen the fire,' or to provide, as it were, an asbestos suit behind which the patient, like some Biblical Shadrach, Meshach or Abednego, protects his tissues from the fire. If this protection is removed prematurely, before the fire has spent itself, the patient and his tissues will react again to the burning. But, if the protection is not discarded until the natural duration of the fire is over, the patient remains largely free of symptoms and apparently 'well' " (Hench, 1952). Unlike other immunosuppressants, glucocorticoids do not significantly inhibit antibody production by B lymphocytes until possibly very high dosages. If glucocorticoids provide incomplete remission of an immune-mediated disorder, other immunosuppressant agents such as the alkylating agent cyclophosphamide may be added to complement the effects of glucocorticoids. Furthermore, if side effects of the glucocorticoids are too great, other immunosuppressants may be added to the regimen. If no clinical response is obtained with glucocorticoid therapy alone, addition of other immunosuppressants is less likely to succeed. Immune-mediated thrombocytopenia and autoimmmune hemolytic anemia are examples of diseases treated with immunosuppressive doses of glucocorticoids.

In small animals, immunosuppression is generally accomplished with prednisolone at 2.2–6.6 mg/kg or the equipotent dosage of dexamethasone at 0.33–1.1 mg/kg q 12 h for induction, and prednisolone at 1.0–2.2 mg/kg every other day for maintenance. Note that, because its duration of action exceeds 24 hours, dexamethasone is acceptable for induction but not for alternate-day maintenance therapy (Ferguson, 1985a, 1985b).

The adverse effects of chronic immunosuppressive doses of glucocorticoid use can be serious. Therefore, clinicians should eventually attempt to maintain a satisfactory therapeutic result with the smallest possible dose of glucocorticoids on alternate days if possible. Nonsteroidal immunosuppressants drugs (e.g., cyclosporine or mycophenolate for immunosuppression) may be used as alternative or adjunctive therapy as necessary.

Chronic Palliative Therapy

Historically, before a wider array of nonsteroidal antiinflammatories became available in the early 1990s, glucocorticoids were commonly used when nonsteroidal antiinflammatory therapy no longer succeeded at managing chronic conditions, such as arthritis in most species or hip dysplasia in dogs. If nonsteroidal analgesics are not satisfactory, glucocorticoids may be used on an intermittent or alternate-day basis. It is important not to administer glucocorticoids erratically, as rapid withdrawal may precipitate signs of lameness or stiffness ("pseudorheumatism") (Fauci, 1976, 1978; Ferguson, 1985a, 1985b).

Alternate-Day Therapy

Side effects of long-term glucocorticoid use can be dramatically reduced by alternate-day therapy. Allowing the HPAA to recover on "off" days provides greater safety if therapy should suddenly be discontinued. Successful use of alternate-day therapy depends upon the therapeutic effects lasting longer than HPAA-suppressive effects. As a result, this approach is not successful for all diseases. Also, true alternate-day therapy is rarely applied to large-animal cases because it is less practical to give large animals agents with low or intermediate potency like prednisolone. Weaning of more-potent agents such as dexamethasone often is accomplished by extending the between-dose interval to as long as 3–4 days in large animals; however, this is technically not considered alternate-day therapy, because full recovery of the HPAA is not allowed on alternate days (Barragry, 1994; Ferguson, 1985a, 1985b).

Several common pitfalls of alternate-day therapy should be avoided. Alternate-day therapy is rarely, if ever, effective as primary therapy. It is usually first necessary to use daily therapy to achieve the desired clinical effect. Alternate-day therapy with long-acting glucocorticoids is not rational. The change to alternate-day glucocorticoid use ideally should be gradual, particularly after prolonged high-dosage therapy. Rapid change to alternate-day use may result in signs of glucocorticoid withdrawal. Finally, alternate-day glucocorticoid therapy may fail if used exclusively; supplemental use of alternative therapy should be considered, particularly on "off" days (Fauci, 1978; Ferguson, 1985a, 1985b).

In inflammatory joint disease caused by infectious or immune-mediated conditions, early aggressive therapy is usually necessary to limit subsequent joint dysfunction. Of course, the primary therapy for immune-mediated arthritis, immunosuppression, can jeopardize the health of patients with infectious arthropathies. So before initiating immunosuppressive therapy, follow a thorough diagnostic plan to exclude infectious causes (Michels and Carr, 1997).

Changing to Alternate-Day Therapy

Because glucocorticoid administration to dogs for longer than 2 weeks generally results in significant loss of adrenal functional reserve, for the sake of this discussion, administration of greater than 0.5 mg/kg/day of prednisolone or an equipotent dosage of a more potent drug for longer than 2 weeks should be considered chronic therapy (Chastain and Graham, 1979). However, when 0.5 mg/kg q 12 h (an antiinflammatory dosage) was administered to dogs for 35 days and stopped abruptly, it took less than 2 weeks for the HPAA to totally recover (Moore and Hoenig, 1992). This contrasts drastically with the experience in humans, where normalization of cortisol secretion and pituitary function may take as long as 6–9 months (Fauci, 1976, 1978). Similar studies have not been performed in large-animal species.

There is no "correct" way to taper an animal from glucocorticoids. The following guidelines are suggested. If the glucocorticoid dosage is large (>1 mg/kg/day prednisolone or an equivalent) or therapy prolonged (>2 weeks in duration), some process of gradually reducing the steroid dosage (i.e., weaning) is indicated. One highly conservative approach is to double the glucocorticoid dose for "on" days and taper the dose for "off" days by 25% per cycle (a cycle may vary from 1 day to several weeks). Another conservative method includes increasing the dose for "on" days by the same amount as the dose for "off" days is decreased. Practical experience indicates that, in many canine patients, rapid tapering has few recognizable side effects unless the animal is severely stressed. Subtle adverse effects may be missed unless the owners and clinician are vigilant. Patient tolerance defines the success of any change. If therapy is for less than 2 weeks, it is probably safe to rapidly taper the dog and have no therapy on "off" days. If clinical signs are observed on "off" days, supplement with a replacement dose of glucocorticoids on those days, or add nonsteroidal therapy. If alternate-day therapy is ineffective, use of a single dose each morning (to mimic diurnal variation) may also minimize adverse effects.

Withdrawal from Glucocorticoids

The identification of clinical signs of glucocorticoid deficiency may be very difficult. Animals cannot complain of minor aches and pains or of mood swings as do people being withdrawn from glucocorticoids. Signs of glucocorticoid withdrawal may include dullness, depression, decreased exercise tolerance, incoordination, unthriftiness and weight loss, loose stools, and behavioral changes. Significant adrenocortical suppression occurs in dogs within 2 weeks of initiating daily glucocorticoid therapy. Therefore, it is reasonable to assume that dogs and cats may require supplementation of glucocorticoids during episodes of stress, such as illness or surgery, particularly if signs of glucocorticoid withdrawal are present. It should be emphasized that short-term use of glucocorticoids in physiological amounts has few risks despite the evidence that these "physiological" quantities significantly suppress the HPAA, resulting in adrenal atrophy (Byyny, 1976; Chastain and Graham, 1979).

Test of Adrenal Reserve

Laboratory tests usually are not necessary to diagnose most cases of iatrogenic adrenal insufficiency; a good history usually indicates the cause of the problem. Occasionally, in the absence of an accurate history or when surgery is considered for a dog with suspected adrenal insufficiency, an ACTH stimulation test is performed to test adrenal functional reserve.

ACTH stimulation test protocol: A venous blood sample is collected in heparin tubes and centrifuged within 15 minutes, with the plasma immediately frozen for later plasma cortisol determination. A dose of 0.25 mg (25 units or an entire vial, though less will work, regardless of the animal's size) of synthetic ACTH (Cortrosyn, Organon) is given intravenously or intramuscularly. For the dog or horse, a postinjection venous blood sample, handled as for the preinjection sample, is collected 1 hour after IV Cortrosyn injection. If cost is a concern, valuable information on adrenal secretory reserve can be obtained by giving ACTH and collecting a blood sample only at the appropriate time after injection. Blood samples are then assayed by a clinical pathology laboratory for plasma cortisol levels. In cats, peak cortisol concentrations should be measured 30 minutes after intravenous ACTH administration.

Interpretation of test results: Healthy unstressed animals have basal plasma cortisol levels in the normal range that increase by 50–100% after ACTH stimulation. Some dogs, after chronic glucocorticoid treatment, may have normal basal cortisol levels but a post-ACTH increase of less than 50%. Such dogs do well until stressed and then require glucocorticoid supplementation (see Section Glucocorticoid Supplementation During Stress). Other dogs may have low basal levels as well as low post-ACTH cortisol levels, indicating a need for continued regular glucocorticoid supplementation as well as additional glucocorticoids during periods of stress (Ferguson, 1985a, 1985b).

Glucocorticoid Supplementation During Stress

Animals with marginally adequate or deficient adrenal function require supplementation of glucocorticoids during periods of stress. In situations of minor stress, such as minor surgery, general anesthesia, a minor illness, or even a visit to the veterinarian, glucocorticoid can be given to avoid collapse and other complications. For example, hydrocortisone or cortisone can be given at 2–5 mg/kg or prednisolone or prednisone at 0.4–1.0 mg/kg. In severely stressful situations, such as in severe illness or major surgery, higher dosages may be necessary. In preparing an animal for major surgery (including adrenalectomy), prednisolone acetate can be given intramuscularly at 0.4–2 mg/kg the night before and the morning of surgery. Alternatively, or in addition, 100–300 mg hydrocortisone can be given by IV drip. These large doses should be gradually reduced within

3–5 days to maintenance levels unless there are complications (Ferguson, 1985a, 1985b).

Considerations for Combination or Sequential Glucocorticoids and Nonsteroidal Antiinflammatory Drugs

Some clinicians have advocated for a "washout time" between switching between two NSAIDs or between a glucocorticoids and a NSAID. While there is good evidence that concurrent administration of a NSAID and a corticosteroid exacerbates GI lesions (Dow et al., 1990; Boston et al., 2003), there is no solid evidence documenting the logic for drug-free intervals moving from one NSAID to another or between NSAIDs and glucocorticoids. Nonetheless, some rational guidelines should be considered. Undoubtedly, if a COX-2-inhibiting drug or glucocorticoid administration follows a known gastroduodenal injury caused by an NSAID or glucocorticoid, there may be increased risk of delayed healing and further injury. However, administration of aspirin and other COX-nonselective drugs may pose a particular risk because they trigger the COX2-dependent synthesis of 15(R)-epi-lipoxin A4 also known as aspirin-triggered lipoxin (ATL), a substance that acts to ameliorate injury to the stomach caused by reduction in protective prostaglandin E1. Simultaneous or subsequent inhibition of COX-2 activity by a selective COX-2 inhibitor or a conventional nonsteroidal antiinflammatory drug (NSAID) removes the formation of ATL by aspirin. In the absence of the protective effects of ATL, the extent of gastric damage is increased. Therefore, coadministration of aspirin and a selective cyclooxygenase 2 inhibitor results in more gastric damage than that induced following administration of either drug alone (Wallace and Fiorucci, 2003). There is indirect evidence that ATL develops in the dog; older studies have shown that after 1–2 weeks of aspirin, GI lesions resolved despite continued administration. High doses of aspirin may over-ride the process of adaptation (Sennello and Leib, 2006). Finally, be sure to consider endocrine effects of glucocorticoids and wean, do not remove precipitously. When serious pain management is needed between NSAIDs, consider other pain-relieving agents: for example gabapentin, fentanyl, codeine, or tramadol.

Miscellaneous or Special Usages

Topical and intralesional usage: Topical and intralesional glucocorticoid administration is occasionally used to manage localized lesions of the skin (see Chapter 47). Despite the route of administration, systemic effects, including suppression of the HPAA, should be expected. Acute inflammatory conditions such as pyotraumatic dermatitis and urticaria are usually managed with nonocclusive, nonheating glucocorticoid preparations. However, chronic conditions are most commonly managed with penetrating glucocorticoid creams and ointments. The potent fluorinated bases such as betamethasone, dexamethasone, triamcinolone, and fluocinolone are the most commonly preferred. The topical, intralesional, or intraarticular use of compounds (e.g., prednisone, cortisone) requiring hepatic activation is of questionable value (Coppoc, 1984; Glaze et al., 1988; Kemppainen, 1986; McDonald and Langston, 1994; Scott, 1982; Scott and Greene, 1974; Wilcke and Davis, 1982).

Intraarticular administration: Intraarticular glucocorticoids have been utilized to manage the orthopedic conditions of traumatic arthritis, myositis, bursitis, and tendinitis. Used primarily in equine medicine to manage joint inflammation and pain, the practice of intraarticular glucocorticoid therapy is controversial and potentially dangerous. Glucocorticoids tend to reduce the pain for a working animal but also diminish chondrocyte collagen and synovial fluid production. The benefits cited for this practice include the reduction of proteolytic enzymes in joint fluid and reduction of joint swelling and discomfort. The hazards include encouragement of further mechanical damage, loss of joint proteoglycan, development of septic arthritis, and inhibition of chondrocyte and osteoblast activity, with the end result being joint or bone breakdown. Intraarticular administration of glucocorticoids leads to systemic absorption and HPAA suppression (Barragry, 1994).

Special considerations for intraarticular glucocorticoid usage in horses: The rationale for intraarticular administration in the horse includes the following: (i) the size of the animal, which requires a large systemic dose of drug to be administered, (ii) the higher incidence of acute arthritis conditions in these animals, and (iii) the adverse systemic effects of corticosteroids. This route is effective for the treatment of synovitis and capsulitis; however, imaging techniques should confirm that there is no prior structural damage, and strict aseptic technique is mandatory. Chronic degenerative joint conditions tend to respond less well than acute ones. Surgery following glucocorticoid therapy can be problematic as corticosteroids slow the rate of healing as described above. Additional forced exercise may compound the joint damage; therefore, at least 3 months should be given to allow damaged cartilage and subchondral bone to heal (Gabel, 1977). In some cases, complete breakdown of the affected joint has occurred during the race following intraarticular glucocorticoid treatment (Tobin, 1979; Upson, 1978). It has been suggested that the rational usage of corticosteroids are effective in prolonging the performance career of carefully selected equine patients, particularly those in which surgical intervention and/or rest will not be of benefit (McKay and Milne, 1976). Furthermore, as previously discussed, glucocorticoid administration is a minor a risk factor for laminitis. In summary, the intraarticular route of administration must be used judiciously (Barragry, 1994). Biochemical and biomechanical properties of osteochondral allograft tissue from juvenile cattle and dogs may be enhanced by the addition of dexamethasone to culture media. These findings may translate to longer shelf life of preserved osteochondral allograft transplantation tissue and increased clinical availability of grafts (Bian et al., 2010). In equine cartilage explants, glucocorticoids had no significant effect on expression of genes studied. Although methylprednisolone acetate and triamcinolone have been shown to have differential effects on chondrocyte metabolism, it is believed that these differences are due to posttranslational and not genomic mechanisms (Caron et al., 2013).

Ophthalmic applications: Glucocorticoids are used topically and subconjunctivally to manage inflammatory conditions of the eye, including retinitis, choroiditis, optic neuritis, and orbital cellulitis (see Chapter 49). These agents stabilize the blood–aqueous and blood–retinal barriers, reducing the leakage of protein into the aqueous that accompanies edema and inflammation. Topical ophthalmic administration of glucocorticoid preparations is also employed to minimize neovascularity and, by inhibiting fibroblast activity, to inhibit corneal scarring, pigmentation, and the formation of synechia.

Topical glucocorticoids are available in solutions, ointments, and suspensions. Penetration, therefore, is determined by two factors: the chemical composition of the base and the vehicle. Except for prednisolone acetate, the alcoholic forms of cortisone, hydrocortisone, and prednisone penetrate the cornea more readily than the acetate ester forms.

Subconjunctival administration of glucocorticoids is used to manage conjunctivitis, keratitis, scleritis, and anterior uveitis. However, it is not the route of choice for diseases of the posterior segment. High concentrations of glucocorticoids can be achieved with subconjunctival administration because the sclera is very permeable to steroids.

Glucocorticoids are contraindicated in corneal ulcers because they slow the process of reepithelialization of the cornea. Furthermore, glucocorticoids enhance the activity of collagenase, which is produced by bacteria like *Pseudomonas* and by leukocytes, and may contribute to the development of "melting" corneal ulcers (Brightman, 1982; Glaze et al., 1988; McDonald and Langston, 1994). Iatrogenic Cushing's syndrome has resulted from topical ophthalmic preparations (Murphy et al., 1990).

Neurological applications: Neurological applications of glucocorticoid therapy are numerous. Potent antiinflammatory action is often necessary to manage acute spinal or CNS trauma, acute cervical or lumbar pain, vestibular disease, acute traumatic and some chronic peripheral neuropathies, polymyositis, and CNS neoplasia (Ferguson, 1985a, 1985b; McDonald and Langston, 1994; Metz et al., 1982; Wilcke and Davis, 1982; Meintjes et al., 1996).

Newer Preparations

Selective glucocorticoid receptor agonists: Given the previously discussed existence of cGR isoforms, future drug development is likely to include qualitatively new drugs, such as selective glucocorticoid receptor agonists (SEGRAMs), but none have become clinically available yet. Several such compounds are under development and are showing promising results. The advantage would be to allow selective therapeutic antiinflammatory benefits associated with transrepression of AP-1 and NF-κB stimulated synthesis of inflammatory mediators, while adverse effects were associated with the transactivation of genes involved in metabolic processes (Buttgereit, 2004; Stahn et al., 2007).

21-Aminosteroids (lazaroids): Neuroprotective effects of GCs at high dosages are independent of GR interaction. 21-aminosteroids have been developed as highly lipophilic drugs, which retain neuroprotective (antilipid peroxidase) effects, in part by reducing fluidity of membranes. They may also appear to scavenge hydroxyl radicals and reduce eicosanoid mediators and tumor necrosis factor, without metabolic effects such as alterations in hematology, glucose, ACTH, or cortisol. Although still largely in development as human pharmaceuticals, their projected use is in acute nervous system trauma, membrane protectants in most forms of shock, and in chronic neurodegenerative diseases (Buttgereit et al., 2004).

Nitrosteroids: This class of glucocorticoids releases low levels of nitric oxide (NO) and it is believed that posttranslational modification of GR by tyrosine nitration is responsible for its enhanced antiinflammatory activity and reduced side effects. Further studies are required in the clinical setting and none have been performed to date in domestic animals (Buttgereit et al., 2004).

"Soft" steroids: Budesonide, ciclesonide, and loteprednol etabonate are examples of "soft" steroids that are designed for delivery near to their site of action to exert their effect, and then undergo metabolism to inactive metabolites. This retrometabolic drug design has the goal of reducing systemic side effects. Budesonide has been used as an orally administered product in dogs and cats primarily for the treatment of inflammatory bowel disease (Pietra et al., 2013) and for feline asthma (Chang et al., 2011). It is absorbed in the intestine and undergoes first-pass metabolism to an inactive metabolite. Approximately 15 times more potent than prednisolone, it still has shown systemic glucocorticoid side effects. It also has been evaluated for topical dermatological therapy (Ahlstrom et al., 2013; Olivry and Bizikova, 2013). Ciclesonide is a new-generation inhaled corticosteroid, which is hydrolyzed by esterases in the upper and lower airways to its pharmacologically active metabolite desisobutyrl-ciclesonide. In human patients, it is used for treating asthma and allergic rhinitis. Limited studies in dogs have shown long-lasting antiallergic (antiasthmatic) effects without influencing the hypothalamic–pituitary axis. Loteprednol is an inactive-metabolite soft steroid that has been used in human medicine as an ophthalmic or inhaled product (Belvisi and Hele, 2003; Bodor and Buchwald, 2006).

Mineralocorticoids

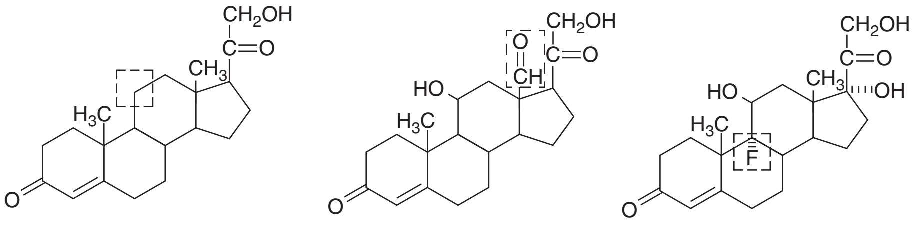
History

In 1855, Thomas Addison first described the clinical manifestations of primary adrenal insufficiency (Addison, 1855); however, it was not until 1929 that crude extracts of adrenal cortex were used in clinical treatment trials of patients with Addison's disease (glucocorticoid and mineralocorticoid deficiency) (Rogoff and Stewart, 1969). In 1937, the adrenocortical steroid 11-desoxycorticosterone was finally produced and made available for treatment of Addison's disease (Thorn et al., 1942). It was able to prevent the urinary sodium loss and was the major therapy for the treatment of Addison's for several years. It was not until the early 1950s that aldosterone was discovered, and it was established that this hormone was involved in water and electrolyte balance (Luetscher, 1956; Simpson et al., 1954). Aldosterone was isolated and synthesized in the mid-1950s (Ham et al., 1955; Simpson et al., 1954). It is by far the most potent of the naturally occurring corticosteroids with regard to water and electrolyte balance.

Secretion and Mechanism of Action

Almost all naturally occurring and synthetically derived corticoids have both mineralocorticoid and glucocorticoid activity but are usually designated on the basis of their predominant activity. Mineralocorticoid hormones are secreted by both the zona glomerulosa and zona fasciculata. The zona glomerulosa produces aldosterone and 18-hydroxycorticosterone under the major control of angiotensin II, while the zona fasciculata produces mainly desoxycorticosterone, 18-hydroxydeoxycorticosterone, and corticosterone under ACTH regulation (Mantero et al., 1990). Most of our knowledge of mineralocorticoid action is derived from studies on the classical target organ for mineralocorticoids, the kidney. Mineralocorticoids bind to a specific receptor, the mineralocorticoid receptor (MR). The MR is a member of the steroid/ thyroid/ retinoid/ xenobiotic/ orphansuperfamily of intracellular receptors, which are ligand-dependent transcription factors. In the absence of hormone the MR resides predominantly in the cytoplasm (Fejes-Tóth et al., 1998) complexed with heat-shock proteins (HSPs) (Couette et al., 1998). Upon hormone binding, there is a conformational change in the receptor's structure, the HSPs dissociate, and the receptor migrates to the nucleus where it binds to the promoter region of target genes and regulates transcription from these genes (Rogerson and Fuller, 2000). The human MR was cloned in 1987 by Arriza (Arriza et al., 1987), and its mRNA was demonstrated in various tissues such as kidney, hippocampus, pituitary, heart, and spleen. The naturally occurring MR ligands are predominantly aldosterone and deoxycorticosterone, although other steroids such as progesterone show high-affinity binding to MR. Aldosterone is the most potent regulator of electrolyte excretion and is essential for life (Sutanto and deKloet, 1991). It is believed to exist in at least five isoforms, which may have different biological activity. Deoxycorticosterone is also a naturally occurring mineralocorticoid with similar binding patterns to MR as aldosterone.

Mineralocorticoids exert their effect in target tissues through interaction with the MR receptor. Hormone-receptor complex binds to chromatin and induces transcription of mRNA, which is subsequently translated to generate proteins. All physiological actions of mineralocorticoids depend on gene activation and new protein synthesis (Johnson, 1992). A two-step model for mineralocorticoid action has been proposed. Changes in membrane electrolyte transport in the kidney are fast (within minutes) and involve the stimulation of Na^+,K^+-ATPase and activation of the Na^+/H^+ exchanger, which leads to Na^+ influx into the cell at the expense of H^+ and K^+, while de novo synthesis of Na^+,K^+-ATPase is a late response (within hours or days). Aldosterone also affects the epithelial Na channel and aldosterone rapidly induces the transcription of gene(s) encoding regulatory protein(s) that increase epithelial Na channel activity in the renal collecting duct and distal colon (Snyder, 2002; Pearce and Kleyman, 2007). The net effect of mineralocorticoid action is, therefore, Na^+ retention, proton excretion, and K^+ excretion (Wehling et al., 1991; Wehling et al., 1992). The addisonian patient typically has hyponatremia, hyperkalemia, and metabolic acidosis.



Deoxycorticosterone Aldosterone Fludrocortisone

Figure 29.9 Structures of common mineralocorticoid drugs used in veterinary medicine. The key elements of structure differing from cortisol are identified by the outlined areas.

Preparations and Properties

The following preparations are currently available for the treatment of mineralocorticoid deficiency:

1) Desoxycorticosterone pivalate (DOCP), a long-acting ester of desoxycorticosterone acetate (DOCA), is available as a sterile suspension for intramuscular injection (Percorten-V$^{\text{TM}}$, Novartis). It has been approved for use in the dog.
2) Fludrocortisone acetate is available for oral use in generic form only. It is manufactured as 0.1-mg tablets (Global Pharmaceuticals), and also from compounding pharmacies in custom-made doses. It has a half-life of approximately 8 hours in humans. Fludrocortisone also has substantial glucocorticoid activity.

Note: Aldosterone is only available for research, not for therapeutic use. The structures of the mineralocorticoid compounds are shown in Figure 29.9.

Therapeutic Use

Historically, DOCA was the treatment of choice for the mineralocorticoid deficiency in acute primary adrenal failure but the drug has been discontinued for many years. For the acute crisis situation or maintenance therapy, either DOCP or fludrocortisone acetate may be used. An initial starting dose of DOCP of 2.2 mg/kg of body weight every 25 days has been recommended (Lynn et al., 1993) for dogs. In the cat a dose of 12.5 mg every 3–4 weeks has been recommended (Greco and Peterson, 1989). These doses and the time intervals of injections may be adjusted depending on the response to therapy as measured by serum Na$^+$ and K$^+$ concentrations.

Fludrocortisone acetate must be administered daily for the treatment of hypoadrenocorticism. In the dog the dose is 0.1–0.5 mg orally twice daily or 0.01 mg/kg divided every 12 hours orally. In the cat the dose is 0.1–0.2 mg divided every 12 hours orally. The dose may have to be adjusted based on weekly electrolyte measurements. Once the animal is stable, rechecks, including serum Na$^+$ and K$^+$ measurement, should be made on a monthly basis. Dogs metabolize this drug rapidly and high doses may be necessary even for less-than-optimal results (Hoenig and Ferguson, 1991b).

Side Effects

Adverse effects of mineralocorticoid replacement therapy are rare but may include hypokalemia, hypernatremia, muscle weakness, and hypertension, particularly in patients with borderline renal disease (Hoenig and Ferguson, 1991b). Because fludrocortisone also has glucocorticoid activity, animals on large doses may show signs of glucocorticoid excess (Lynn et al., 1993). It is important that any fluid deficits be corrected prior to treatment with mineralocorticoids.

Adrenolytic Drugs and Steroid Synthesis Inhibitors

Therapy for Hyperadrenocorticism

Spontaneous hyperadrenocorticism is characterized by excess secretion of the glucocorticoid cortisol. In 85–90% of cases in the dog and the majority of cases in the horse, the primary species suffering from this condition, the cause is excess ACTH production by the pituitary. The term “Cushing’s disease” is the term used when the adrenal glands are bilaterally hypertrophied and producing excess cortisol in response to overproduction of ACTH by the pituitary corticotrophs. In the horse, an intermediate lobe pituitary tumor is the most common cause. Accordingly, in dog and horse, there have been attempts to reduce ACTH production with dopaminergic compounds (like bromocryptine mesylate or pergolide mesylate) or the antiserotoninergic agent cyproheptadine. The experience with these agents has largely been unsatisfactory in the dog due to toxicity and lack of efficacy. In the horse, pergolide seems to be a more effective treatment than cyproheptadine or bromocryptine (Schott, 2002).

Low hypothalamic dopamine concentrations have been observed in dogs with pituitary-dependent hyperadrenocorticism. As such, dopamine deficiency has been proposed as an underlying etiology for this condition. L-Deprenyl (Anypril®, Pfizer Animal Health), a monoamine oxidase B enzyme inhibitor that inhibits the breakdown of dopamine, has been approved for the treatment of uncomplicated pituitary-dependent hyperadrenocorticism in the dog (Figure 29.10).

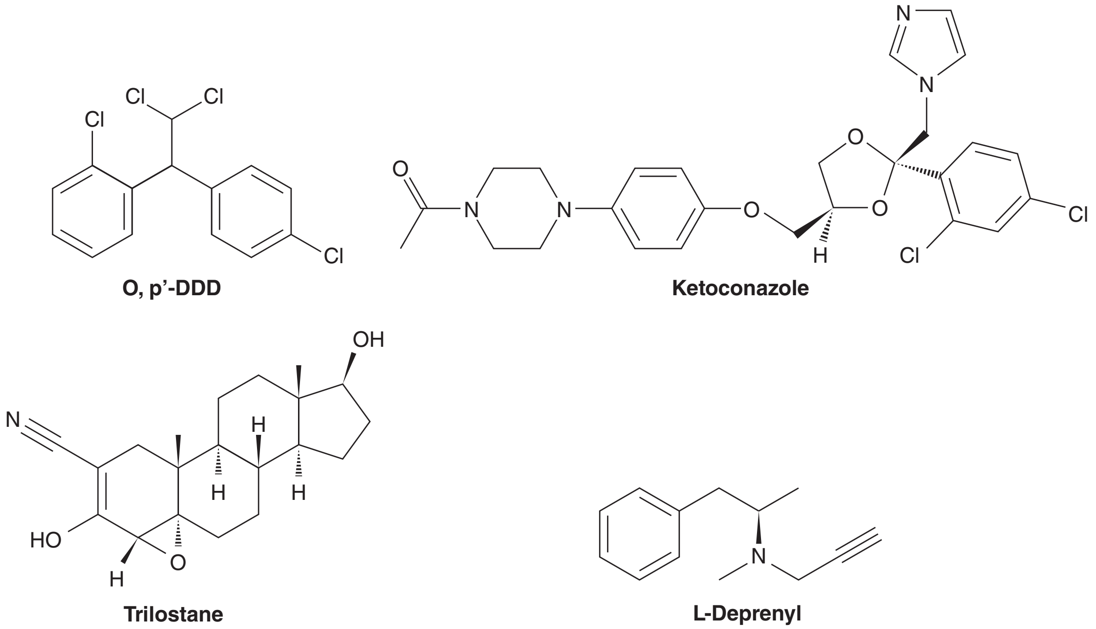


Figure 29.10 Structures of antiadrenal drugs.

Medical therapy for hyperadrenocorticism in the dog has been primarily aimed at reducing glucocorticoid production by the adrenal cortex. The two most frequently used drugs are mitotane and trilostane (Hoenig and Ferguson, 1991a; Neiger et al., 2002). Both drugs are used for hyperadrenocorticism regardless of etiology. A study has shown that the survival time of dogs treated with mitotane or trilostane was not significantly different (Arenas et al., 2014). Trilostane has also been used in horses (McGowan and Neiger, 2003). Hyperadrenocorticism rarely occurs in cats and the response to medical therapy has been mostly inconsistent. A study, however, indicates that trilostane was well tolerated and ameliorated signs of hyperadrenocorticism in a small number of cats (Mellett-Keith et al., 2013).

Mitotane

Chemistry and Mechanism of Action

Mitotane (1-(*o*-chlorophenyl)-1-(*p*-chlorophenyl)-2,2-dichlorethane; *o,p*'/4-DDD) (Figure 29.10) is a compound that is chemically similar to the insecticides DDD and DDT and leads to a relatively selective destruction of the zonae fasciculata and reticularis by an unknown mechanism.

Metabolism

Clinical studies in human patients indicate that approximately 40% of orally administered mitotane is absorbed, while the remainder is recovered in the feces. Similar studies are not available for the dog or cat.

Preparations and Properties

Mitotane (Lysodren; Bristol-Myers Oncology Division) is available in 500-mg scored tablets.

Therapeutic Uses

The cytotoxic effect of mitotane to the dog adrenal cortex was first described in 1959 (Villar and Tullner, 1959); however, it was not until 1973 that mitotane was used therapeutically in veterinary medicine (Lorenz et al., 1973; Schechter et al., 1973) and it became the most commonly used form of treatment for pituitary-dependent hyperadrenocorticism (Peterson, 1983). It has also proven to be efficacious in cases with adrenal neoplasia (Kintzer and Peterson, 1989; Feldman et al., 1992; Helm et al., 2011). Usually 25–50 mg/kg are given daily or divided twice daily for 7–10 days. The lower dose is usually given to dogs with concomitant disease, such as diabetes (see below in this section). The goal of this so-called loading period is to decrease the capacity of the adrenal cortex to the point that cortisol secretion becomes minimal and the animal is unable to respond to exogenous ACTH with an increase in cortisol secretion. If, after the loading period, the ACTH stimulation test indicates little or no response of the adrenal glands to ACTH and cortisol concentrations are low, the dog is kept on the same dose of mitotane, and a maintenance dose is given once weekly. To reduce side effects, it is advisable to divide the dose and give it over several days. If the ACTH stimulation test indicates a normal or even exaggerated response, the treatment with mitotane is continued and the dog retested at 5- to 10-day intervals until the desired response is obtained. In some cases, the mitotane dose needs to be increased to 75 mg/kg or 100 mg/kg to obtain the desired response. Higher loading doses are generally necessary to decrease cortisol concentrations in dogs with adrenal neoplasia and are followed by higher maintenance doses as well. Cortisol-secreting tumors seem to be more resistant and sometimes even unresponsive to the adrenolytic effect of mitotane.

Diabetic animals need to be monitored carefully while on mitotane treatment because the decrease in cortisol concentrations makes the animal more sensitive to insulin. For that reason, some clinicians prefer to use 25–35 mg/kg of mitotane instead of 50 mg/kg in the diabetic. Dogs on maintenance treatment need to be reevaluated regularly. An ACTH stimulation test is the most accurate assessment of adrenal functional reserve. If the ACTH test shows normal or exaggerated cortisol response, the animal should undergo “loading” again for several days, with an increase in the maintenance dosage. Cushingoid cats have shown an inconsistent response to mitotane treatment (Hoenig and Ferguson, 1991a; Kintzer and Peterson, 1989; Schechter et al., 1973; Valentin et al., 2014).

Side Effects

The side effects of mitotane at routine therapeutic doses are usually mild and may consist of gastrointestinal problems such as vomiting and anorexia, mild hypoglycemia, CNS depression, and mild liver damage with increases in alkaline phosphatase. However, in some cases the rapid fall in cortisol levels may lead to weakness, diarrhea, and lethargy. In rare cases, the zona glomerulosa is affected by mitotane, and electrolyte abnormalities compatible with Addison’s disease are seen (Kintzer and Peterson, 1989; Schechter et al., 1973).

Trilostane

Chemistry and Mechanism of Action

Trilostane (4α,5α-Epoxy-17β-hydroxy-3-oxoandrostane-2α-carbonitrile) produces suppression of the adrenal cortex by reversibly inhibiting enzymatic conversion of steroids by 3-β-hydroxysteroid dehydrogenase/δ-5,4 ketosteroid isomerase, thus blocking synthesis of adrenal steroids, including cortisol and aldosterone. The effect on aldosterone is less than that on cortisol (Wenger et al., 2004).

Metabolism

Trilostane is metabolized by the liver in people. There are no reports to date that describe the metabolism in dogs, cats, or horses.

Preparation and Properties

Trilostane (Vetoryl®, Dechra) is available in 30, 60 and 120-mg capsules. It should be stored at room temperature in airtight, light-resistant containers. Pregnant women should wear gloves when handling the drug (trilostane has been shown to cause abortion in pregnant monkeys and all users should wash their hands after handling the capsules).

Therapeutic Uses

Trilostane has been used for treatment of hyperadrenocorticism (pituitary dependent and adrenal dependent) in dogs (Neiger et al., 2002; Ruckstuhl et al., 2002; Wenger et al., 2004; Arenas et al., 2014), cats (Neiger et al., 2004; Valentin et al., 2014), and horses (McGowan and Neiger, 2003). In dogs, trilostane has been effective in reducing polydipsia/polyuria in over 90%, and polyphagia in over 80%. Trilostane causes a significant reduction in pre- and post-ACTH cortisol concentrations. It also leads to a significant decrease in alanine aminotransferase and alkaline phosphatase. Potassium concentrations increase but not usually to a level that requires medical intervention. Similarly, in horses, trilostane caused a reduction in polyuria/polydipsia and recurrent or chronic laminitis.

Trilostane is administered once daily at 2–10 mg per kg in dogs. Because accurate dosing with capsules is difficult, miniature dogs (<5 kg) usually receive 30 mg, small dogs (<20 kg) receive 60 mg; medium size dogs (<40 kg) 120 mg, and large dogs 240 mg. This needs to be adjusted according to clinical signs and cortisol values. The goal of therapy is to decrease post-ACTH cortisol concentrations measured 4–6 hours after administration of trilostane to 27–55 nmol/l (1–2 μg/dl).Some dogs may need twice-daily administration for control (Bell et al., 2006).

Cats have been treated successfully with an oral dose of 0.5–12 mg/kg every 12 or 24 hours, indicating a wide range in individual efficacy of the drug (Valentin et al., 2014). Others have suggested a mean initial dose of trilostane of 4.3 mg/kg if given once daily and 3.3 mg/kg if given twice daily (Mellett Keith et al., 2013). The dose in horses is 0.4–1.0 mg/kg once daily.

Side Effects

Trilostane seems to be generally well tolerated. Diarrhea, vomiting, and lethargy have been described, which are usually mild and self-limiting. However, acute deaths have also been seen in a small number of dogs (Neiger et al., 2002), and necrosis of the adrenal cortex (Chapman et al., 2004; Reusch et al., 2007) has been described. Interestingly, ultrasonographically, adrenal glands increase in size in dogs on trilostane (Mantis et al., 2003). This increase may be caused by the trophic effect of higher ACTH concentrations, which are due to lower negative feedback. Trilostane has been approved by the FDA for use in dogs in 2008.

Ketoconazole

Chemistry and Mechanism of Action

Ketoconazole (*cis*-1-acetyl-4-[4-[[2-(2,44-dichloro phenyl)-2-(1H-imidazol-1-ylmethyl)-1,3-dioxolan-4-yl] methoxyl]phenyl]piperazine) (Figure 29.10) is an imidazole derivative whose major effect is to inhibit sterol synthesis in fungi (Schechter et al., 1973). In mammalian cells, it inhibits the conversion of lanosterol to cholesterol by inhibition of cytochrome P450–dependent enzyme systems (Loose et al., 1983). Ketoconazole also inhibits the synthesis of hormones from cholesterol such as cortisol, estradiol, and testosterone (Pont et al., 1940, 1982; Willard et al., 1986). In male dogs it greatly increases serum progesterone concentrations (Willard, 1989). Ketoconazole is a widely used antifungal agent in veterinary medicine and is fully discussed in Chapter 38.

Preparations and Properties

Ketoconazole (Nizoral®, Jannsen-Cilag) is available in tablet form, each containing 200 mg ketoconazole base, for oral administration. It is soluble in acids.

Metabolism

Ketoconazole requires an acidic environment for the dissolution of the drug. Its bioavailability is therefore decreased in patients on antacids. After oral ketoconazole administration, maximal blood concentrations occur 1–2 hours later. There is considerable variation in the bioavailability of the drug in dogs (Baxter et al., 1986). Approximately 50% of ketoconazole is excreted unchanged in the feces, and the rest is metabolized mainly by the liver. Inactive metabolites are excreted primarily in the feces; a small amount is excreted in the urine.

Therapeutic Uses

Ketoconazole is used to decrease cortisol concentrations in dogs with pituitary-dependent hyperadrenocorticism and cortisol-secreting adrenal neoplasms. The drug is expensive but in the past, before trilostane became available, it was a valuable alternative in those cases where mitotane was ineffective. It was also used as initial therapy prior to adrenalectomy in order to control the hyperadrenocorticism and reduce the risk of anesthesia and surgery. However, about 25% of dogs will not respond to this therapy. The recommended dose is 15 mg/kg twice daily. Because ketoconazole inhibits cortisol synthesis only reversibly, it should be given on a daily basis.

No consistent therapeutic effect of ketoconazole has been demonstrated in the cushingoid cat. The dose in the cat is 10 mg/kg twice daily.

Side Effects

The main side effects are vomiting and anorexia. Hepatic enzymes can transiently increase. In rare cases, a reversible hepatopathy with icterus may be seen (Willard, 1989). Gynecomastia and azoospermia have been reported in human patients (DeFelice et al., 1981). Ketoconazole is teratogenic and should not be used in pregnant animals.

L-Deprenyl

Chemistry and Mechanism of Action

L-Deprenyl hydrochloride (selegiline hydrochloride) is phenylisopropyl-*N*-methylpropinylamine (Figure 29.10) and is an irreversible inhibitor of monoamine oxidase B. L-Deprenyl is thought to decrease the metabolism of dopamine and also other catecholamines, to inhibit the reuptake of dopamine, and to increase its synthesis. It is hypothesized that the increase in dopamine concentrations decreases ACTH secretion from the pituitary and in turn cortisol secretion from the adrenal gland. In a study by Milgram and coworkers (1995), however, brain levels of dopamine were unaffected when dogs were given L-deprenyl for 3 weeks at different doses. The authors concluded that although dopamine was not increased, L-deprenyl could still affect dopaminergic transmission through one of its metabolites, phenylethylamine, whose levels were increased in dogs on L-deprenyl.

Preparations and Properties

L-Deprenyl (Anipryl®, Zoetis) is available for oral administration as white, convex tablets containing 2, 5, 10, 15, or 30 mg.

Metabolism

The metabolism of L-deprenyl in the dog is unknown. In humans, L-deprenyl is metabolized to amphetamine and metamphetamine; amphetamine concentrations also were increased in dogs on L-deprenyl (Reynolds et al., 1978). Pharmacokinetic analysis in four dogs indicated that the drug had a short half-life, which was attributed to high clearance and large volume of distribution of the drug. After oral administration, the bioavailability of the drug was less than 10% (Mahmood et al., 1994).

Therapeutic Uses

L-Deprenyl is rarely used anymore for the treatment of uncomplicated Cushing's disease and its primary indication is for the treatment of cognitive dysfunction. In 125 cases with naturally occurring pituitary-dependent hyperadrenocorticism, L-deprenyl was shown to be effective in controlling clinical signs associated with the disease such as panting, polyuria, polydipsia, obesity, reduced activity, abdominal distention, and others. The initial dose is 1 mg/kg body weight once daily; this dose might have to be increased if a response is not seen after 4 weeks. The maximum dose is 2 mg/kg body weight per day. It is recommended that the drug be administered for a 2- to 3-month period to allow sufficient time to assess its clinical usefulness. Should the dog's condition deteriorate during that time or should the dog show complications due to high cortisol levels, L-deprenyl should be discontinued and treatment with mitotane initiated. Although the company claims that 80% of dogs with hyperadrenocorticism respond favorably to L-deprenyl treatment, a study in a very small group of dogs suggests that only about 20% show an improvement of the clinical signs associated with the disease (Reusch et al., 1999). It has been argued that only cushingoid dogs with pituitary pars intermedia tumors might respond to this treatment. Pars intermedia tumors account for approximately 30% of pituitary tumors in dogs with Cushing's disease (Peterson, 1999).

Side Effects

L-Deprenyl is a very safe drug. The following adverse effects were noted infrequently in dogs on long-term treatment: vomiting, diarrhea, hyperactivity, anorexia, diminished hearing, weight loss, anemia, polydipsia, and weakness.

Drugs Influencing Glucose Metabolism

Margarethe Hoenig

Insulin

History

Diabetes mellitus has been recognized for centuries as a debilitating disease, characterized by the excretion of "sweet urine" (mellituria), polydipsia, wasting of tissue, and the development of ketoacidosis, hyperosmolar coma, and death. The role of the pancreas in the development of diabetes was first recognized in 1886 when Minkowski and von Mering produced diabetes by total pancreatectomy in the dog. In 1921, Banting and Best extracted the active compound from pancreas and showed that it was able to control hyperglycemia in diabetic dogs and humans. Insulin was prepared for the first time in crystalline form in 1926 by Abel, and it took 34 more years until its amino acid sequence was demonstrated by Sanger. Finally, in 1963 insulin was synthesized by Meyenhofer and coworkers, and in 1964 by Katsoyannis and coworkers. In 1967, Steiner discovered that insulin was synthesized as a larger precursor, proinsulin. An even larger molecule, named preproinsulin, was identified as a precursor for proinsulin in 1976 by Chan and coworkers (for a detailed review see Bliss, 1983). These research efforts have culminated in the biosynthesis of human insulin by recombinant DNA techniques, allowing large-scale production of the hormone in 1983 (Frank and Chance, 1983; Johnson, 1983).

Spontaneous diabetes has been reported in many species. Diabetes is a major health problem and one of the leading causes of death in humans. In animals, it occurs most frequently in the dog and cat, with an incidence of approximately 0.5–1%. Overt diabetes is rare in horses, cattle, and sheep, although obese horses may develop metabolic syndrome, which might include abnormal glucose concentrations. Isolated cases of diabetes have been reported in mules, ferrets, pigs, newts, buffalos, monkeys, and fish (Stogdale, 1986). Diabetes also has been reported in several breeds of birds (Stogdale, 1986). Diabetes in humans has been classified into two major categories, which are of interest to veterinary medicine: type 1 diabetes, previously called insulin-dependent diabetes mellitus or juvenile-onset diabetes, and type 2 diabetes, previously called noninsulin-dependent diabetes mellitus or maturity-onset diabetes. Based on glucose-tolerance testing (Kaneko et al., 1977; O'Brien et al., 1985), it has been determined that most diabetic dogs and cats are insulin deficient.

Chemistry and Biosynthesis

Insulin is produced in the beta cells of the islets of Langerhans in the endocrine pancreas. The islet also contains glucagon-secreting alpha cells, somatostatin-secreting delta cells and PP or F cells, which secrete pancreatic polypeptide. The beta cells compose about 60–80% of the islet. The endocrine cells are arranged in a nonrandom distribution, with beta cells forming a central core surrounded by a mantle of the other three cell types in some animals and humans (Bonner-Weir and Orci, 1982). In the cat, the beta cells are located in the periphery (O'Brien et al., 1986), while in the horse, the alpha cells form a central core (Helmstaedter et al., 1976) surrounded by beta cells.

Insulin exists initially as preproinsulin, which is cleaved to proinsulin in the endoplasmic reticulum. Proinsulin is a large polypeptide consisting of an A and B chain and a connecting peptide (Figure 30.1). By proteolytic cleavage, four basic amino acids and the connecting peptide are removed, and proinsulin is converted to insulin (Steiner et al., 1969). This reduces the molecular weight from 9000 (proinsulin) to one of 6000 (insulin) and one of 3000 (C-peptide). This conversion occurs soon after proinsulin is transported to the Golgi complex, where it is packaged into secretory granules. These granules therefore contain an equimolar amount of insulin and C-peptide. In the secretory granules, insulin is complexed with zinc and stored.

The amino acid sequence of insulin shows little species variation. Human insulin differs from porcine and rabbit insulin by a single amino acid, whereas dog insulin is identical to porcine insulin. Bovine insulin differs from

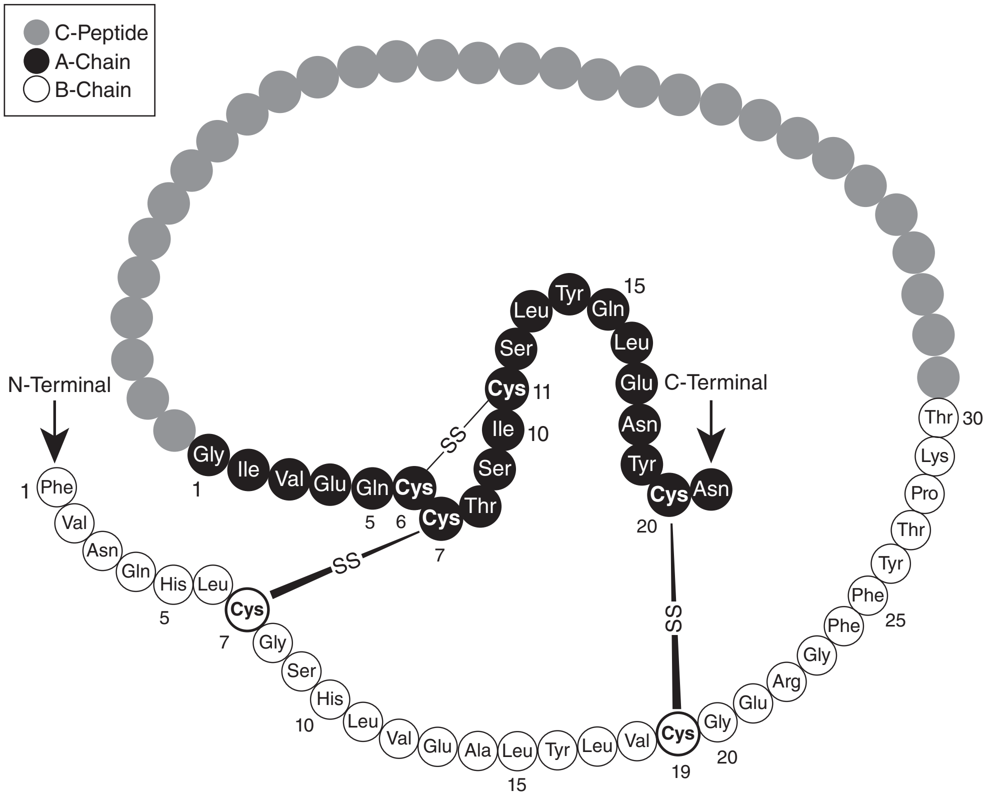

Figure 30.1 Proinsulin.

human insulin by three amino acids and from feline insulin by one amino acid (Neubauer and Schoene, 1978; Porte and Halter, 1981; Hoenig et al., 2006a). Antiserum directed against insulin of one species usually cross-reacts with insulin of other species. Antiinsulin serum generally also cross-reacts with heterologous proinsulin, while C-peptide has no immunoreactivity against insulin antiserum. The biological activity of proinsulin, however, is much less than that of insulin. Feline proinsulin has been cloned and expressed (Hoenig et al., 2006a).

Secretion

The secretion of insulin from the beta cell occurs through the process of exocytosis in which there is fusion of the secretory granule with the plasma membrane. Insulin secretion is highly regulated primarily by glucose, but also by other fuels, hormones, and neurotransmitters (Porte and Halter, 1981). On a cellular level, insulin release stimulated by glucose and other fuels is thought to be initiated by closure of ATP (adenosine triphosphate)-dependent K channels, which leads to depolarization of the beta cell and influx of calcium into the cytosol through voltage-gated calcium channels (Arkhammar et al., 1987; Cook et al., 1988). The increase in cytosolic free calcium triggers pulsatile insulin secretion. In addition, augmentation of this response occurs by both a K^+-ATP channel-independent Ca^{2+}-dependent pathway and K^+-ATP channel-independent Ca^{2+}-independent pathways of glucose action (Henquin, 2011). The pathway that is Ca^{2+} dependent but independent of ATP-K channels is called the amplification pathway. The exact mechanism is not understood (for review see Straub and Sharp, 2002). Insulin is released from the beta cell in a pulsatile fashion. It is thought that these rapid oscillations are generated through intraislet mechanisms, because they can be seen even in isolated islets and beta cells (Berman et al., 1993). Pulsatile secretion becomes abnormal in diabetes; however, pulsatility can be restored by beta cell rest (Laedtke et al., 2000).

In both type 1 and type 2 diabetes, islet function and insulin secretion are abnormal. It is now clear that in both types a loss of beta-cell mass has occurred and that the fundamental difference between the two major types of diabetes lies in the etiology of the beta-cell dysfunction and its severity but not its presence or absence (Porte, 1991). It is controversial whether a reduction in beta cell mass or function play the major role in the pathogenesis of type 2 diabetes (for review see Meier and Bonadonna, 2013). It appears that both occur together and are tightly related. Insulin resistance, frequently seen with obesity in humans and cats (Kahn et al., 2006; Hoenig et al., 2006b) is an important concomitant factor in type 2 diabetes and puts an additional stress on the beta cell. However, the insulin resistance of obesity alone is not sufficient to cause diabetes. This is shown by the fact that over 80% of obese people are not diabetic; a similar assessment has not been made in cats. It is not known how many obese cats actually become diabetic. Obesity increases the risk of diabetes; however, most obese cats have normal glucose control because they counteract peripheral insulin resistance with a decrease in endogenous glucose output by the liver (Kley et al., 2009; Hoenig et al., 2011, 2012, 2013). It is interesting that, while the prevalence of obesity in people and cats is about equal, about 8% of humans develop type 2 diabetes, whereas the prevalence of diabetes in cats is <1%. The reason for this discrepancy is not known.

Evidence suggests that disordered insulin secretion may contribute to development of insulin resistance and hence represent an initiating factor in the progression to type 2 diabetes (Schofield and Sutherland, 2012). An early marker of beta cell dysfunction is a loss of pulsatility of insulin secretion. This leads to hepatic insulin resistance and higher uncleaved proinsulin concentrations (for review see Wahren et al., 2012). An early marker is also a change in the proinsulin/insulin secretion ratio (Haffner et al., 1997). In cats and humans, among a few others, the increase in insulin release from a reduced beta-cell mass in type 2 diabetes is associated with release and deposition of islet amyloid polypeptide, leading to further loss of beta cells (Porte and Kahn, 1989; Hoenig et al., 2000a). It is thought that the majority of dogs have a form of diabetes similar to type 1 diabetes in people, that is involving a genetic component, which is influenced by environmental input. The possibility of a genetic basis for canine diabetes has been suggested by the occurrence of the disease in dog families, and the presence of DLA haplotypes that seem to confer risk of diabetes. In type 1 diabetes in people, the loss of beta cells is caused primarily by immune-mediated destruction (MacLaren et al., 1989). Beta-cell antibodies are present in approximately 50% of naïve diabetic dogs (Hoenig and Dawe, 1992). In later studies, 4/30 dogs were found to be positive for antibodies against the 65-kDa isoform of canine glutamic acid decarboxylase and 3/30 also had antibodies against the insulinoma-associated antigen-2 (IA-2), both frequently found in human type 1 diabetics (Davison et al., 2008a). In another study, 5/40 newly diagnosed dogs had antibodies against insulin (Davison et al., 2008b). Beta-cell antibodies have not been demonstrated in diabetic cats (Hoenig et al., 2000b).

Insulin secretion can also become autonomous, resulting in hyperinsulinemia associated with hypoglycemia. Insulin-secreting tumors (adenomas or carcinomas; also called insulinomas) occur infrequently and have been described in the dog, cat, ferret, cattle, and a pony (Capen, 1990). The diagnosis of an insulinoma can be difficult, but frequently it can be made on the basis of an inappropriately high serum insulin concentration. In humans, the diagnosis is often made based on high proinsulin and/or C-peptide concentrations (Chammas et al., 2003).

Mechanism of Action

Insulin is the most potent physiological anabolic agent. In insulin-responsive tissues, it facilitates cellular uptake and metabolism of glucose. Insulin promotes the synthesis of glycogen, protein, and fat and is involved in the uptake of ions such as K into the cell. Insulin exerts its effect by binding to specific receptors on the plasma membrane of cells. The insulin receptor is a tetrameric structure consisting of two subunits: an alpha and a beta subunit. Two of each of these subunits are joined together via disulfide bonds. Both subunits are glycosylated and exposed to the extracellular milieu; only the beta subunit is exposed to the intracellular environment. The insulin receptor has tyrosine kinase activity. Binding of insulin leads to autophosphorylation of the receptor and these phosphorylated Tyr residues serve as docking sites for downstream effectors (Le Roith and Zick, 2001; Schinner et al., 2005). Once the insulin receptor kinase is activated, the presence of insulin is not necessary for its continued activity. The receptor is inactivated by dephosphorylation.

Despite our knowledge of insulin–receptor interaction, our understanding of molecular events that link the insulin–receptor to the regulation of cellular metabolism is poor. Some, but not all, of the actions are due to the phosphorylation or dephosphorylation of target proteins on serine and threonine residues. The mediation of the mitogenic responses involves the mitogen-activated protein (MAP) kinase pathway, whereas the metabolic responses of insulin, such as glucose transport, involve phosphatidyl-inositol-3 (PI3)-kinase. Diabetes has also been linked to alterations in the function of both endoplasmic reticulum (Kaneto et al., 2005) as well as mitochondria (Lowell and Shulman, 2005).

Metabolism

The existence of a relatively specific insulin-degrading enzyme (IDE, insulinase, insulin-specific protease) has been reported by several investigators (for a review see Duckworth, 1990). Insulin-degrading activity has been found in essentially all tissues examined, and high activity has been seen in liver, kidney, muscle, brain, fibroblasts, and red blood cells. The enzyme seems to be located predominantly in the cytoplasm but can be found in other subcellular compartments. Plasma membrane preparations also contain this enzyme. Some receptor-bound insulin is degraded on the membrane, while some insulin is released intact from the receptor, and some is

Tresiba® (Insulin Degludec)	Recombinant human insulin analog, DNA origin	U200		

internalized with the receptor, and insulin degradation is then initiated in endosomes. The degradation of insulin via this process is rapid. Other enzymes may also be involved in the degradation of insulin, and their role and factors controlling insulin-degrading activity in various tissues and disease states needs to be examined.

Preparations and Properties

The biological activity of insulin preparations is documented using a bioassay that is based on the capacity of insulin to lower blood glucose concentrations. All but one insulin preparation used in human medicine have been standardized at 100 U/ml; a U 500 (500 U/ml) regular insulin preparation is still available from Eli Lilly. All insulin preparations used for humans are of recombinant origin, either containing the exact amino acid sequence of human insulin, or mutations thereof. This has led to a variety of new insulins with different action times. Regular human insulin, lispro, glulisine, and aspart can be given intravenously. There are two insulins that have been approved for veterinary use: ProZinc® is a human recombinant protamine zinc insulin, and Vetsulin® is a pork zinc insulin and is currently the only animal-derived insulin still available on the US market. Both are approved for use in cats; Vetsulin in addition is for use in dogs. Both of these insulins contain 40 U/ml and are administered subcutaneously. For correct dosage, insulin preparations are administered with syringes that are calibrated for the appropriate standardization (e.g., U 100 syringes, U 40 syringes). All commercially available insulins in the United States contain no more than 25 parts per million of proinsulin. The insulin preparations currently available are summarized in Table 30.1.

Based on action profiles, insulin preparations can be divided into fast, intermediate, and long acting. Generally, lispro and aspart, as well as the regular insulin preparations, have a quick onset of action (15-30 minutes) and short duration, whereas the NPH (neutral protamine Hagedorn), glargine, detemir, protamine zinc, and the pork zinc insulin preparations have a longer onset and duration of action. There is, however, considerable species and individual variation in the insulin action profiles. It is important for the practitioner to realize that the time course of action of any insulin preparation may not only vary considerably between different individuals, but also in the same individual from day to day (Hoenig and Ferguson, 1991; Church, 1981). It is also important to realize that the pharmacokinetics change with different doses. The time periods listed by manufacturers should only be considered as initial guidelines. Individual responses to insulin and the “fine-tuning” of insulin therapy have to be assessed by measuring blood glucose concentrations at frequent intervals, yielding what is called a “glucose curve”. In order to decrease stress effects, glucose monitoring also can be performed by measuring interstitial glucose concentrations using a continuous glucose monitoring system (e.g., Guardian Real-Time; Medtronic). Of the newer short-acting insulin preparations, lispro has been used successfully for the treatment of ketoacidotic dogs (Sears et al., 2012). There are currently no reports of the clinical use of aspart in pets. The pharmacokinetics of insulin aspart are similar to those of regular insulin when given intravenously in people. The plasma half-life is 11 minutes with insulin aspart and 12 minutes with regular insulin. When given subcutaneously, there is also little difference between the two insulins. However, both show great individual variations in plasma concentrations (Plum et al., 2000).

Glargine and detemir have been used extensively in diabetic cats (Weaver et al., 2006; Roomp and Rand, 2009; Roomp and Rand, 2012) and also in dogs (Sako et al., 2011; Fracassi et al., 2012; Hess and Drobatz, 2013). Although labeled as "long-acting" insulin preparations, they usually need to be given twice daily for optimal glucose control. The dosage of detemir is generally less than that of other insulin preparations.

Insulin, thus far, needs to be injected for the effective treatment of diabetes. The short-acting insulin preparations can be injected intravenously, intramuscularly, and subcutaneously; the intermediate and long-acting insulin preparations are for subcutaneous injection. The preferred injection site is the flank for those injections. Some of the intermediate and long-acting insulin preparations, but not detemir and glargine, are suspensions and need to be gently mixed before administration. It is recommended to shake pork zinc insulin vigorously before the first use. The shelf life of most insulin preparations is 28 days when stored at room temperature. If refrigerated, unopened bottles last until the expiration date of the vial.

Attempts have been ongoing to produce insulins that do not require injection. Exubera®, which was produced by Pfizer, Sanofi-Aventis, and Nektar Therapeutics, was a rapid-acting, dry-powder type of insulin that was delivered to the lungs via a special bong-shaped inhaler device, and received FDA approval in 2006. It was withdrawn from the market in 2007 because of weak sales. Oral-lyn® has been developed by Generex. It is a novel oral (buccal) insulin spray product, which is delivered into the human mouth by way of the company's proprietary RapidMist drug delivery system. It completed phase III clinical trials in India in 2013 and is awaiting approval by the Indian authorities. It remains to be seen if such a preparation could be used in pets.

Therapeutic Uses

Treatment of Diabetes Mellitus in Dogs and Cats

Insulin deficiency is characterized by increased catabolism. The breakdown of glycogen, increased endogenous glucose output, and decreased utilization of glucose in peripheral tissues, especially muscle and adipose tissue, leads to hyperglycemia. Protein breakdown fuels gluconeogenesis, and fat breakdown leads to increased fatty acids in blood and their transfer primarily to the liver, where they are used for energy, ketone body or very low-density lipoprotein (VLDL) production. They can also be reesterified leading to fatty liver.

Treatment of diabetes must be adjusted to the clinical presentation of the animal. Usually, two broad forms can be differentiated: uncomplicated and complicated diabetes mellitus. For practical purposes, complicated diabetics are those that cannot take food orally, such as the vomiting ketoacidotic patient or the comatose hyperosmolar patient (Hoenig and Ferguson, 1991).

The goal of treatment of a diabetic dog is to maintain blood glucose concentrations in a high normal to mildly hyperglycemic range for most of the day to alleviate the biochemical effects and clinical signs of insulin deficiency and avoid hypoglycemia. In cats, the treatment regimens are controversial. Some clinicians advise to maintain blood glucose concentrations in a normal to mild hyperglycemic state, similar to what is recommended for diabetic dogs; that is, the blood glucose should stay between 5 and 15 mmol/l (90-270 mg/dl) for most of the day (Reusch, 2010), and the nadir should be between 90 mg/dl and 160 mg/dl, avoiding the dangers of hypoglycemia in a patient that cannot convey the more subtle signs of low blood glucose. Others have proposed an insulin treatment regimen even more rigorous than what is desirable in humans (Roomp and Rand, 2012), and advocated to achieve glucose concentrations in diabetic cats between 2.8 and 5.5 mmol/l (50 and 100 mg/dl), that is a range where cats may experience biochemical as well as clinical hypoglycemia. The goal of this regimen is to increase remission rates. While these investigators have reported higher remission rates than others, without blinding the studies and providing detailed information about the health status of the patients entering those studies and the feeding protocols, a comparison between the success of a particular treatment regimen is not possible. Furthermore, the dangers of hypoglycemia cannot be ignored and might compromise the quality of life of both owner and pet.

The fast-acting insulin preparations are used for the complicated diabetic patient. These animals can be treated with low-dose constant rate insulin infusions (see Table 30.2 for treatment protocol) or intramuscular insulin injections with regular insulin or lispro insulin using 0.1 units/kg as needed to keep blood glucose concentrations at approximately 200 mg/dl. Glargine, a long-acting insulin preparation, has also been used for the treatment of ketoacidosis in cat and was given intramuscularly as well as subcutaneously (Marshall et al., 2013). Because of glargine's long duration; however, such a protocol would eliminate the ability to quickly intervene.

The intermediate and long-acting insulin preparations are used in the diabetic that is able to eat and drink without vomiting. As stated above, it is important to realize that each animal reacts differently to a given insulin preparation, which makes glucose control challenging

Table 30.2 Low-dose, continuous IV infusion protocol for the treatment of diabetic ketoacidosis. Source: Modified from Macintire, 1993 and Sears et al., 2012.

1. Place intravenous catheter.
2. Start fluid therapy (0.9% NaCl or Normosol R; consider replacement and maintenance fluid requirements, as well as supplementation with K and/or P as needed). Rehydrate the animal.
3. [Insert urinary catheter and attach to a closed monitoring system.]
4. Add regular insulin or lispro insulin (2.2 units/kg/day) to 250 ml of saline solution. Use pediatric infusion set or infusion pump for accurate administration. Use protocol shown below.
5. Monitor blood glucose concentrations every 1 hour.
6. Monitor urinary output.
7. Monitor electrolytes every 8 hours. Adjust if necessary.
8. Change saline solution to 2.5% dextrose in 0.45% saline, when blood glucose reaches approximately 250 mg/dl (13.8 mmol/l). Continue to administer insulin. Supplement K and/or P as needed. Adjust fluid rate and glucose concentration of the fluid as follows:

Blood glucose (mg/dl)	IV fluids	Insulin rate (ml/hour)
>250	0.9% saline	10
200–250	0.9% saline 2.5% dextrose	7
150–200	0.9% saline 2.5% dextrose	5
100–150	0.9% saline 5% dextrose	5
<100	0.9% saline 5% dextrose	stop

9. Keep animals on this regimen until they are able to eat without vomiting.
10. Stop insulin infusion in the evening. Start treatment of the uncomplicated diabetic the next morning.

for the veterinarian. However, most animals need twice-daily insulin administrations for good control, regardless of the fact that a so-called intermediate or long-acting insulin preparation has been used. It is prudent to maintain a treatment regimen for several days before trying to adjust the time and dose of insulin or the time of feeding, unless insulin leads to hypoglycemia. It may take several weeks before an animal shows a consistent response to a given preparation. Hypoglycemic episodes make it more difficult to regulate a diabetic because of the insulin-antagonistic effects of counterregulatory hormones, which are secreted in response to low blood glucose concentrations (called Somogyi rebound).

Treatment of Ketosis in Cattle

Insulin is a powerful antiketogenic agent and has been used as adjunct treatment in ketosis therapy. It has been suggested that insulin therapy is particularly beneficial in those cases of ketosis that occur within the first week of lactation and are nonresponsive to glucose or glucocorticoid therapy alone (Herdt and Emery, 1992). A dose of 200–300 IU of protamine zinc insulin per animal, repeated as necessary at 24 to 48-hour intervals, was administered.

Adverse Effects

Acute hypoglycemia may result from excessive insulin dose, especially in the presence of inadequate food intake. The brain is particularly sensitive to glucose deficiency, and nervous system dysfunction is seen. Initially, confusion, nervousness, trembling, or hyperexcitability may be seen, which progress to convulsions if the hypoglycemia is not treated. Karo® syrup or other glucose-containing solutions can be used orally; however, the intravenous administration of dextrose solutions may be necessary to alleviate the hypoglycemic symptoms. Glucagon may also be used intramuscularly or as a constant rate infusion (see Section Glucagon; Fischer et al., 2000).

The body itself combats hypoglycemia through the release of insulin-antagonistic hormones, primarily catecholamines, glucagon, glucocorticoids, and growth hormone. This frequently leads to hypoglycemia-induced hyperglycemia, the so-called Somogyi rebound, mentioned in Section Treatment of Diabetes Mellitus in Dogs and Cats (Cryer and Gerich, 1990).

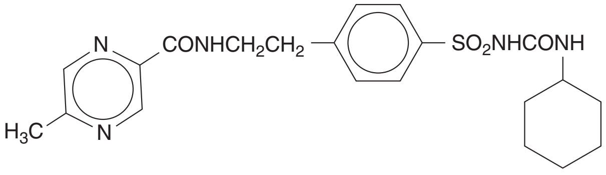
Antibody formation against insulin has been documented in diabetic dogs (Davison et al., 2003) and diabetic cats (Hoenig et al., 2000b). While this has not been examined in dogs, in cats the insulin dose was not different in the presence or absence of antibodies, and the clinical significance therefore seems to be minor.

Oral Hypoglycemic Agents

Sulfonylureas

History

During World War II, Janbon and colleagues, in 1942, found that certain sulfonamide derivatives being used to treat typhoid fever caused hypoglycemia. After the end of the war, derivatives of these antibiotics were first used to treat patients with diabetes. Studies by Loubatieres showed that sulfonylureas did not alter blood glucose concentrations in pancreatectomized dogs and juvenile diabetics (i.e., type 1), which suggested that sulfonylureas



Glipizide

Figure 30.2 Chemical structure of the sulfonylurea glipizide.

stimulated the pancreas to secrete insulin (Loubatieres, 1946). Indeed, sulfonylureas have become the major therapeutic agent used to treat type 2 diabetes in humans until recently. In type 2 diabetics insulin secretion is still present, at least initially, although insufficient to control blood glucose concentrations. In most diabetic dogs and cats the insulin-secretory capacity of the beta cells is lost, and they require insulin for treatment.

Chemistry

The chemical structure of the most commonly used sulfonylurea in veterinary medicine, glipizide, is shown in Figure 30.2. Oral sulfonylurea agents available in the United States are listed in Table 30.3. Sulfonylureas differ in potency, duration of action, metabolism, and side effects.

Mechanism of action

In the pancreatic beta cells, sulfonylureas inhibit ATP-dependent potassium (K^+) channels in the plasma membrane. This results in depolarization and release of insulin (Antomarchi et al., 1987). Because ATP-sensitive K^+ channels also exist in other tissues, sulfonylureas exert tissue-specific responses through the activation of the channels. The extrapancreatic effects of sulfonylureas have been described in detail by Gerich (1989). Sulfonylurea therapy augments the ability of insulin to inhibit hepatic glucose production and to stimulate glucose utilization. It is unclear if these effects are direct effects of the drugs or secondary to the reduced hyperglycemia caused by improved insulin secretion.

Table 30.3 Oral sulfonylurea agents available in the United States

Tolbutamide: Orinase (Upjohn) and generics
Tolazamide: Tolinase (Upjohn) and generics
Chlorpropamide: Diabinese (Pfizer) and generics
Acetohexamide: Dymelor (Lilly) and generics
Glyburide: Micronase (Pfizer) and DiaBeta (Sanofi-Aventis)
Glipizide: Glucotrol (Pfizer)
Glimepiride: Amaryl (Sanofi Aventis) and generics

Metabolism

In people, sulfonylureas are readily absorbed from the gastrointestinal tract and are highly protein-bound. Glipizide has a half-life in plasma of approximately 2–4 hours, but its hypoglycemic effects may persist for up to 24 hours. It is metabolized in the liver, and its inactive metabolites are excreted in the urine (Gerich, 1989). Sulfonylureas should not be administered in patients with renal or hepatic insufficiency. Glipizde interacts with other drugs and its effectiveness might either be increased (e.g., with H_2 antagonists, anticoagulants, sulfonamides, salicylates) or decreased (e.g., thyroid medication, phenothiazines, corticosteroids, beta blockers).

No studies on the pharmacokinetics of glipizide have been done in the cat or dog. Studies in healthy cats showed an immediate release of insulin after oral administration. Peak insulin concentrations were achieved 15 minutes later, and baseline concentrations were reached again after 60 minutes (Miller et al., 1992). In our own studies, the insulin concentration peaked 30 minutes after glipizide administration and did not return to baseline levels until several hours later (Hoenig, unpublished). Glipizide is usually administered orally. A study has evaluated transdermal administration of glipizide. The absorption was low and inconsistent and it was concluded that a transdermal preparation cannot be recommended at this time (Bennett et al., 2005).

Preparations and properties

The preparation used most frequently in veterinary medicine is glipizide (Glucotrol®; Pfizer). It is marketed as 5 and 10-mg tablets.

Therapeutic uses

Glipizide has been advocated as an antidiabetic agent for the cat (Miller et al., 1992). The drug seemed to be effective in some cats and is given at a dose of 2.5–5 mg BID.

For glipizide to be effective, it is necessary for beta cells to still have the capacity to release insulin. Therefore, in theory, this drug should only be administered in those cases in which insulin secretion has been documented (with glucose/glucagon stimulation tests, etc.). However, it has been shown that glipizide accelerates amyloid deposition in cat islets (Hoenig et al., 2000a), which confirmed evidence in rats that these drugs may actually be harmful (Kahn et al., 1993). It is therefore prudent to treat all diabetic cats with insulin at this time (i.e., the insulin-deficient patient whose beta cells no longer can secrete insulin and the patient who still has insulin but whose secretion rate is insufficient to control blood glucose concentrations) until other oral antihypoglycemic agents have been evaluated and shown to be effective.

Adverse effects

Hypoglycemia is the most frequently observed side effect of sulfonylureas in humans; however, severe life-threatening hypoglycemic reactions are rare. The hypoglycemic reactions may be potentiated by drugs that are highly protein-bound. In cats, vomiting, hypoglycemia, icterus, and an increase in alanine aminotransferase (ALT) have been reported (Feldman et al., 1997). They were all reversible when the drug was either discontinued or the dosage decreased. Other side effects seen in humans include increased cardiovascular mortality, gastrointestinal disturbances, allergic skin reactions, and hematological changes (Gerich, 1989).

Metformin

Metformin (*N,N*-dimethylbiguanide; Glucophage®, Bristol-Myers Squibb; and generics) is an oral antihyperglycemic agent used primarily in the management of type 2 diabetes in people. Metformin reduces blood glucose concentrations primarily by reducing hepatic glucose output and by improving peripheral sensitivity to insulin without affecting insulin secretion. It does not cause hypoglycemia at therapeutic doses. Although the pharmacokinetic profile of metformin has been established in the cat (Michels et al., 1999) and is similar to that in people, data on the efficacy of the drug in clinical diabetes cases are sparse. When metformin was used in five diabetic cats (Nelson et al., 2004), only one showed a beneficial response after 8 weeks of treatment, three showed no response, and one cat died unexpectedly. The drug is eliminated primarily by renal clearance in the cat (Michels et al., 1999) and should not be used in cats with significant renal dysfunction.

Thiazolidinediones

Thiazolidinediones (TZDs, or "glitazones") are orally administered insulin sensitizers marketed for use in human type 2 diabetes. TZDs are agonists of the peroxisome proliferator activated receptor gamma (PPARγ) (Tontonoz and Spiegelman, 2008), a transcription factor belonging to the nuclear hormone receptor superfamily. PPARγ plays a key regulatory role in metabolism, cellular differentiation, and cell growth, and is crucial for adipocyte development, lipid transport and storage, and whole-body glucose homeostasis (Menendez-Gutierrez et al., 2012). For the TZDs, adipose tissue is likely to be a major site of action through direct PPARγ activation. PPARγ is abundant in mature adipocytes, and many more genes are differentially expressed in adipose tissue after TZD treatment than are affected in other tissues such as muscle and liver (Way et al., 2001; Rasouli et al., 2012). Proteins known to be upregulated in adipocytes by TZD treatment include glucose and fatty acid transporters, fatty acid binding and sequestration proteins, metabolic enzymes, and many others (Lefterova et al., 2010; Tontonoz and Spiegelman, 2008).

In addition to their benefits regarding glycemic control, TZDs improve indices of beta-cell function in human diabetes (Gastaldelli et al., 2007). Clinically, the consequences of beta-cell functional improvement and preservation by the TZDs are durable long-term glycemic control (DeFronzo, 2010) and reduction of diabetes risk in susceptible populations (DeFronzo et al., 2011). In a large cohort of humans with impaired glucose tolerance ("prediabetics"), pioglitazone reduced the risk of conversion to diabetes by 72% (DeFronzo et al., 2011).

Among the thiazolidinedione compounds, troglitazone (Rezulin®, Parke Davis) was the first to become widely available (Nolan et al., 1994). The serious liver side effects forced the discontinuation of the use of this drug. Pioglitazone (Actos®, Takeda) and rosiglitazone (Avandia®, GlaxoSmitKline) have been approved by the FDA in 1999 for the treatment of type 2 diabetics. Because of an increased incidence of cardiovascular adverse events, rosiglitazone was removed from the US market and placed on a restricted prescription list. Pioglitazone is now the only TZD available for general prescription. The pioglitazone pharmacokinetics have been evaluated in cats (Clark et al., 2012). It was found that it was rapidly absorbed after oral administration, with a mean bioavailability of 55%. Volume of distribution of the drug after IV administration was similar to that seen in other species, while clearance was increased and half-life decreased relative to humans. It was shown in a randomized placebo-controlled study that 3 mg/kg pioglitazone administered for 7 weeks significantly improved insulin sensitivity and lowered serum triglyceride and cholesterol concentrations in obese cats. No adverse effects attributable to pioglitazone were evident in the otherwise healthy obese cats at this dosage and duration (Clark et al., 2014). There are no reports about the efficacy of this drug in diabetic cats or in cats with lipid disorders.

Acarbose

Acarbose (Precose®, Bayer) is an alpha glucosidase inhibitor, a term applied to inhibitors of alpha amylase, which digests starch, and of brush border oligo- and disaccharidases, which cleave off glucose. Acarbose delays and reduces postprandial hyperglycemia after a carbohydrate meal. It has been used in human diabetic patients in combination with insulin and oral antihyperglycemic agents but also as monotherapy. Gastrointestinal disturbances such as diarrhea, flatulence, and abdominal pain are the major side effects (Scheen and Lefebvre, 1998). The pharmacokinetics of acarbose has been established in the dog (Ahr et al., 1989), and a small number of diabetic dogs needed less insulin when treated with acarbose

(Robertson et al., 1998). It has also been used in diabetic cats in combination with a low-carbohydrate diet (Mazzaferro et al., 2003).

Sodium–Glucose Cotransporter 2 Inhibitors

Sodium–glucose cotransporters (SGLTs) are a large family of membrane proteins that transport glucose, among other substances, across the brush-border membrane of the intestinal epithelium and proximal renal tubules (Ghezzi and Wright, 2012). Two SGLTs are most important in affecting glucose transport in the intestine and kidney. The low-capacity, high-affinity transporter SGLT1 is expressed mainly in the small intestine and late proximal tubules of the kidney, whereas the high-capacity, low-affinity transporter SGLT2 is found primarily in the early proximal tubules and is responsible for most of the glucose reabsorption (Kurosaki and Ogasawara, 2013). Inhibitors of SGLT2 have been investigated for their use in the treatment of diabetic hyperglycemia three decades ago. At that time it was shown that phlorizin, a nonselective SGLT inhibitor, could correct hyperglycemia and insulin resistance in diabetic rats (Rossetti et al., 1987). Today, several SGLT2 inhibitors (canagliflozin, empagliflozin, and dapagliflozin) are on the human market. They can be used alone but are also produced in combination with metformin or a DPP-4 inhibitor (see Section Glucagon-Like Peptide 1 and Dipeptidyl Peptidase 4 Inhibitors). They are currently approved for the treatment of type 2 diabetes in people, resulting in an increased amount of glucose being excreted in urine. They lower HbA1c without increasing the risk of hypoglycemia, and they contribute to reductions in body weight and blood pressure (Mudaliar et al., 2015). Side effects in humans include genitourinary infections and ketoacidosis, although the latter appears to be rare. There are currently no published reports about their use in diabetic pets.

Glucagon

History

Although the existence of a pancreatic hyperglycemic hormone was postulated in 1923 by Kimball and Murlin (1923), it was not until 1955 that Staub and coworkers succeeded in purifying glucagon (Staub et al., 1955). In 1957, Bromer and coworkers identified its amino acid sequence (Bromer et al., 1957).

Chemistry and Biosynthesis

Glucagon is a polypeptide hormone containing 29 amino acids. Its structure is highly preserved in different species, and the different glucagons differ usually only by one or two amino acids. Glucagon is synthesized in the alpha cells of the islets of Langerhans as a prohormone with a molecular mass of 18 kilodaltons. The exact mechanism of glucagon secretion into the blood is still controversial (Walker et al., 2011). Glucagon, which bears striking structural similarity to secretin, gastric inhibitory peptide, and vasoactive intestinal peptide, is coreleased with two major proglucagon fragments. Glucagon-like immunoreactive peptides are also synthesized in the gastrointestinal tract.

Secretion

Glucagon is a hyperglycemic hormone and as such is antagonistic to the action of insulin. The special arrangement of beta and alpha cells in the islet makes a close interaction of both hormones possible, and both glucagon and insulin exert a major regulatory function on metabolism (for review, see Walker et al., 2011). It seems that, for many metabolic effects, the ratio of insulin to glucagon is important for the regulation of cellular responses (Smith, 1989). In general, glucagon secretion is stimulated by low glucose concentrations, by protein intake, and by lowered fatty acid concentrations. Glucagon secretion is also under control of intestinal hormones and neurotransmitters (Unger and Orci, 1989).

Mechanism of Action

Glucagon is a major antagonist of insulin action. Glucagon stimulates glycogenolysis, gluconeogenesis, and lipolysis. Administration of glucagon leads to a rapid increase in intracellular cyclic adenosine monophosphate (cAMP) concentrations, which is followed by activation of cAMP-dependent protein kinase and subsequent substrate phosphorylation (Smith, 1989).

Metabolism

Glucagon is degraded in liver, kidney, plasma, and at its receptor on the plasma membrane. Its half-life in plasma is approximately 3–6 minutes (Unger and Orci, 1989).

Preparations and Dosage

Glucagon, in the past, was extracted from beef and pork pancreases, but now it exists in recombinant form. Glucagon for injection (Eli Lilly) contains glucagon as the hydrochloride and is dispensed in 1 mg vials. It is packaged with diluent containing glycerin, Water for Injection, and hydrochloric acid. One mg is usually administered to dogs for insulin-induced hypoglycemia.

Therapeutic Uses

Glucagon can be used for the treatment of insulin-induced hypoglycemia when dextrose is unavailable. It is only useful as a hyperglycemic agent in those patients that have sufficient hepatic glycogen. Glucagon should not be used in hypoglycemia due to insulinoma or in patients with pheochromocytoma, because it can induce hormone release from the tumors. In humans it is also used for radiographic and endoscopic examination of the gastrointestinal tract, because it acts as a smooth muscle relaxant. Glucagon has been used in small animals for double-contrast gastroscopy (Evans and Biery, 1983); however, a beneficial effect for endoscopic examinations in the dog could not be confirmed (Matz et al., 1991).

Adverse Effects

Glucagon is relatively free of adverse effects. Generalized allergic reactions have been reported in human patients after glucagon administration. Anecdotally, vomiting has been observed in some dogs and cats.

Glucagon-Like Peptide 1 and Dipeptidyl Peptidase 4 Inhibitors

Glucagon-like peptide 1 (GLP-1) is an incretin that augments insulin secretion after food intake. It also inhibits glucagon release and gastric emptying. Because of its poor stability, it cannot be used therapeutically. However, exendin-4 (Exenatide; Byetta®, Eli Lily/Amylin), a synthetic version of a peptide isolated from the saliva of the Gila monster, has been shown to bind and activate the known human GLP-1 receptor and is now used therapeutically for the treatment of type 2 diabetics. In people, it is injected subcutaneously twice daily within 60 minutes before the morning and evening meal. An exenatide extended-release formulation (Bydureon®**)** has been approved in 2012 for once-weekly treatment of type 2 diabetes. In an unblinded study, the treatment effect of exenatide added to glargine insulin in diabetic cats was not significantly greater than that seen in glargine placebo-treated cats (Riederer et al., 2016). Because the half-life of GLP-1 is very short, a new class of drugs has been developed, the dipeptidyl peptidase 4 (DPP-4) inhibitors. Their mechanism of action is thought to result from increased incretin levels (GLP-1 and glucose-dependent insulinotropic polypeptide, GIP)leading to increased insulin concentrations (Valk, 2007). Sitagliptine (Januvia®, Merck)was the first to be approved for use in human type 2 diabetics; now there are several more. It has been suggested that GLP-1 based therapies, including DPP-4 inhibitors, lead to pancreatitis and malignant transformation of cells, resulting in an increased risk for pancreatic and thyroid cancer (Elashoff et al., 2011). There are no reports of their use in diabetic pets.

Somatostatin

History

Somatostatin was isolated from ovine hypothalamus in 1973 by Brazeau and coworkers (Brazeau et al., 1973). Soon it became evident that somatostatin was not only present in hypothalamus but also in other tissues, including the pancreas (Hökfeldt et al., 1975; Arimura et al., 1975). It became apparent that the islet delta cells, first described by Bloom (1931), secreted this hormone, which inhibited insulin and glucagon secretion (Koerker et al., 1974).

Chemistry and Biosynthesis

Somatostatin is synthesized as a high-molecular weight precursor, which is differently processed in a tissue-specific manner. In the pancreas and hypothalamus it is cleaved mainly to a 14-residue peptide containing an internal disulfide bridge, whereas in the gastrointestinal tract the predominant form is a 28-residue peptide. Very little is yet known about the regulation of its biosynthesis.

Secretion

Much still needs to be learned about the regulation of somatostatin secretion. In the pancreas, somatostatin may act in a paracrine or endocrine manner when released from the delta cells (Hauge-Evans et al., 2009).

Mechanism of Action

The mechanism of action by which somatostatin inhibits insulin and glucagon release from the islet cells is not well understood. There is evidence that somatostatin inhibits insulin release by decreasing Ca influx through voltage-gated calcium channels, an action which is mediated through a G-protein (Hsu et al., 1991). It has been shown that somatostatin inhibits insulin gene expression through a posttranslational mechanism, however, at concentrations well above those measured in the peripheral blood. Somatostatin release is stimulated by most nutrients, including glucose, amino acids, and a fat–protein meal. Somatostatin also inhibits growth hormone release and a variety of gastrointestinal hormones (for a review see Long, 1987).

Metabolism

Somatostatin is metabolized in the liver (Ruggere and Patel, 1985). It has an apparent half-life of 3–5 minutes (Harris, 1994).

Preparations and Dosage

The only preparation available with pharmacological actions similar to somatostatin is the synthetic agent octreotide acetate (L-cysteinamide; Sandostatin® Injection, Sandoz Pharmaceuticals), a cyclic octapeptide prepared as a clear solution of octreotide acetate in buffered saline for deep subcutaneous injection. In humans, peak concentrations are reached within 0.4 hours; the half-life is approximately 1.5 hours in humans and approximately 75 minutes in dogs (for a review see Long, 1987). The duration of action of octreotide is variable but can extend up to 12 hours.

Therapeutic Uses

In humans, octreotide acetate is used most frequently in patients with VIP(vasoactive intestinal polypeptide)oma and carcinoid.

In dogs, octreotide has been used for the treatment of some insulinomas and for gastrinomas. Not all of the tumors treated responded to octreotide, likely because of the absence of specific receptors. Octreotide has not proven to be useful in the treatment of acromegaly. The dose for the treatment of insulinomas is 10–20 μg BID to TID; in gastrinomas 20–60 μg TID have been recommended (Lothrop, 1991). Octreotide has also been used in ferrets and cats with insulinomas with mixed results.

Adverse Effects

In humans, gastrointestinal problems are most frequently encountered after octreotide administration. Side effects in dogs have not been described.

Miscellaneous

Diazoxide (Proglycem®; Merck) is 7-chloro-3-methyl-2*H*-1,2,4-benzothiadiazine 1,1-diazoxide. It is a white powder practically insoluble in water. This nondiuretic benzothiadiazine inhibits insulin release from the beta cell by increasing the permeability to potassium, thereby hyperpolarizing the cell membrane (Trube et al., 1986). It also has extrapancreatic effects and promotes hepatic glycogenolysis and decreases glucose uptake in the liver (Altzuler et al., 1977). It is used in the treatment of insulin-secreting tumors. The initial dose of diazoxide is 10 mg/kg body weight divided into two daily doses. This dose can be increased gradually but should not exceed 40 mg/kg daily. Diazoxide is available as 50-mg capsules or as a suspension containing 50 mg/ml diazoxide.

Toceranib phosphate (Palladia®, Zoetis) (Z)-5-[(5-Fluoro-2-oxo-1,2-dihydro-3H-indol-3-ylidene)methyl]-2,4-dimethyl-N-(2-pyrrolidin-1-ylethyl)-1H-pyrrole-3-carboxamide phosphate is a tyrosine kinase inhibitor. It has been approved for the treatment of mast cell tumors in dogs but has been anecdotally also used to treat insulinomas. There are no scientific studies about the success of this drug in dogs with insulinomas.

Antiseptics and Disinfectants

Megan E. Jacob

Introduction

Cleansers, antiseptics, and disinfectants play critical roles in preventing infectious disease transmission in veterinary medicine. From use as a presurgical scrub to disinfection after an outbreak, these products are relied upon by veterinarians for safe and effective germicidal activity. The beneficial effects of cleansing or disinfecting practices have been known for many years; the efficacy of hand washing was demonstrated as early as the 1840s by Ignaz Semmelweis, a Hungarian obstetrician. Following Pasteur's identification of infective agents as the cause of disease, Joseph Lister suggested the use of antiseptics in the field of surgery. His treatment of the hands with 1 : 20 carbolic lotion and his initiation of methods for chemical sterilization of bandages, dressings, and surgical instruments and for antisepsis of wounds began aseptic surgery.

Cleansers, antiseptics, and disinfectants are differentiated by their intended use and characteristic properties, not by their chemical content. A cleanser aids in physical removal of foreign material and is not necessarily a germicide. An antiseptic is a biocide applied to living tissue, whereas a disinfectant is a biocide applied to inanimate objects. Because certain antiseptics may be inactivated on inanimate surfaces and because certain disinfectants are hazardous to living tissue, the two should not be used interchangeably; however, these products may still have a very similar chemical content. Even products with the identical active chemical moiety may be formulated in such a way (e.g., exposure time, concentration) as to prevent their interchangeable use. Products formulated as disinfectants (and sanitizers or sterilants) to be used on inanimate surfaces, objects, or instruments are regulated by the Environmental Protection Agency (EPA). Antiseptics for use on living tissue must be registered with the Food and Drug Administration (FDA), along with some chemicals used on critical and semicritical devices.

Different cleaning, antiseptic, and disinfectant protocols exists for many different clinics, farms, procedures, and uses in veterinary medicine; no one compound is applicable, appropriate, or effective for every use.

Cleansers

Cleansers contain surfactants or detergents that remove dirt and contaminating organisms by solubilization and physical means. Cleansers are often a critical step to proper disinfection or antisepsis as removing gross contamination from an area prior to disinfection or antisepsis treatment maximizes their efficacy. Depending on the application and use, cleansing may be sufficient.

Cleansers can be classified into three types based on the presence and charge of the hydrophilic portion of the molecule: anionic, cationic, and nonionic. Soaps are anionic surfactants of the general structure $\text{R-COO}-\text{Na}^+$. Dissociation in water to $\text{R-COO}-$ liberates a molecule with both a hydrophilic and a hydrophobic portion, which can emulsify and solubilize hydrophobic dirt, fat, and protoplasmic membranes. Once solubilized, this contamination can be rinsed away with water. The ability to solubilize membranes renders soaps antibacterial against gram-positive and acid-fast bacteria. The anionic nature of soaps, however, causes them to be inactivated in the presence of certain positive ions such as free Ca^+ in hard water and in the presence of cationic detergents. The mixture of soaps and quaternary ammonium compounds forms a precipitate, which terminates the activity of both compounds. Inclusion of antiseptic compounds in soap preparations has given them a wider antibacterial spectrum.

The quaternary ammonium compounds (QACs) are examples of cationic surfactants with germicidal activity. These compounds have been widely used as disinfectants (see Section Examples of disinfectant use in Veterinary Medicine). Cationic surfactants combine readily with proteins, fats, and phosphates and are thus of limited value in the presence of serum, blood, and other tissue debris (Huber, 1988). In addition, use with materials such as gauze pads and cotton balls makes them less germicidal owing to absorption of the active ingredients.

Antiseptics

An antiseptic is a chemical agent that reduces the microbial population on skin and other living tissues. Because in most cases its mechanism of action involves nonspecific disruption of cellular membranes or enzymes, caution must be taken not to harm host tissue. An ideal antiseptic would have a broad spectrum of activity, low toxicity, high penetrability, would maintain activity in the presence of pus and necrotic tissue, and would cause little skin irritation or interference with the normal healing process.

The use of antiseptics has been suggested in situations which require maximal reduction of bacterial contamination (Larson, 1987) such as when defense mechanisms are compromised after surgery, during catheterization or insertion of other invasive implants, and in immunocompromised states due to immune defects, cytotoxic drug therapy, extreme old or young age, or extensive skin damage (burns and wounds).

Disinfectants

Disinfection is a process that eliminates most, if not all, pathogenic organisms, excluding spore forms, from an inanimate object. Disinfection is sometimes incorrectly confused with sterilization, a process that completely eliminates all microbial forms by a physical or chemical means. True chemical sterilization necessitates the use of an EPA-registered agent capable of killing all infective organisms, including fungal and bacterial spores, usually within 10 hours. Sometimes, however, chemical sterilants can be considered disinfectants when shorter exposure periods are used. The treatment of objects that are too large to soak in disinfectant, such as cabinets, exam tables, chairs, lights, and cages, is considered surface disinfection. Immersion disinfection is the immersion of smaller objects in disinfectant for sufficient time to kill the majority of contaminating, pathogenic organisms.

The ideal characteristics of a disinfectant includes a broad spectrum, fast action, activity in the presence of organic material (including blood, sputum, and feces), compatibility with detergents, low toxicity, low cost, ease of use, and residual surface activity. They should not corrode instruments or metallic surfaces or disintegrate rubber, plastic, or other materials, and should be odorless and economical (Molinari et al., 1982).

The ability to kill different classes of microorganisms further categorizes disinfectants into high, intermediate and low levels. High-level disinfection destroys all microorganisms except high concentrations of bacterial spores. Intermediate-level disinfection inactivates acid-fast microorganisms, including *Mycobacterium tuberculosis*, most viruses and fungi, but not necessarily bacterial spores. Low-level disinfection kills most bacteria, some viruses, and some fungi, but not tubercle bacilli or bacterial spores. In addition, low-level disinfection usually occurs in less than 10 minutes.

A second classification system is intended to divide instruments and patient-care items into three categories based on risk of infection involved in their use (Spaulding, 1968). In this system, items are classified as: (i) critical – those that enter or penetrate skin or mucous membranes (e.g., needles, scalpels), usually at a sterile site; (ii) semicritical – those that touch intact mucous membranes (e.g., anesthesia equipment, endoscopes); and (iii) noncritical – those that do not touch mucous membranes but may contact intact skin (e.g., stethoscopes, cages, tables, food bowls). In general, items classified as critical should be sterilized, semicritical items require high-level disinfection, and noncritical items require low to intermediate-level disinfection.

Popular Antiseptic and Disinfecting Agents

Alcohol

Alcohols are one of the most popular antiseptic and disinfecting products, used every day in veterinary clinics and laboratories. Although many alcohols are germicidal, the two most commonly used as disinfecting agents are ethyl and isopropyl alcohol. These compounds are both lipid solvents and protein denaturants. They kill organisms by solubilizing the lipid cell membrane and by denaturing membrane cellular proteins. Alcohols are most effective when diluted with water to a final concentration of 70% ethyl or 50% isopropyl alcohol by weight. It is thought that at greater concentrations, initial dehydration of cellular proteins makes them resistant to the denaturing effect (Molinari and Runnel, 1991). Alcohols have excellent antibacterial activity against most vegetative gram-positive, gram-negative, and tubercle bacillus organisms but do not inactivate bacterial spores. They are active against many fungi and viruses, principally enveloped viruses due to alcohol's lipid-solubilizing action.

The alcohols are not recommended for high-level disinfection or chemical sterilization due to their inactivity against bacterial spores and reduced efficacy in the presence of protein or other bioburden. Blood proteins are denatured by alcohol and will adhere to instruments being disinfected. Fatal *Clostridium* spp. infections have occurred postoperatively that were the result of contaminated surgical instruments that had been disinfected with alcohol containing bacterial spores (Nye and Mallory, 1923). After repeated and prolonged use, alcohols can damage the shellac mounting of lensed instruments, can swell or harden rubber and certain plastic tubing (Rutala, 1990), and can be corrosive to metal surfaces. Alcohols are flammable; thus caution must be taken in their storage and when used prior to electrocautery or laser surgery. In deciding between ethyl and isopropyl alcohol, it is important to consider isopropyl's inactivity against hydrophilic viruses, its less corrosive nature, and the abuse potential for ethyl alcohol (grain alcohol).

Both isopropyl and ethyl alcohol are also commonly used, effective antiseptics, with only subtle differences in their action. Because their effectiveness is drastically reduced by organic matter such as feces, mucus, and blood, they are most effective on "clean" skin. They produce rapid reduction in bacterial counts (Lowbury et al., 1974), with contact times of 1–3 minutes, resulting in elimination of almost 80% of organisms. Rapid evaporation limits contact time; however, residual decreases in bacterial counts are seen to occur after the alcohol has evaporated from the skin. Although alcohols are among the safest antiseptics, toxic reactions have been reported in children. Alcohol can be drying to the skin and can cause local irritation. In efforts to minimize this drying effect, emollients such as glycerine have been added with good results (Larson et al., 1986).

Halogens

Iodine and chlorine both demonstrate antimicrobial activity and are used as antiseptics or disinfectants. Elemental iodine has germicidal activity against gram-positive and gram-negative bacteria, bacterial spores, fungi, and most viruses. It exerts these lethal effects by diffusing into the cell and interfering with metabolic reactions and by disrupting protein and nucleic acid structure and synthesis. Iodine has a characteristic odor and is corrosive to metals. It is insoluble in water and thus is prepared in alcohol (tincture) or with solubilizing surfactants ("tamed" iodines). Tincture of iodine, used as early as 1839 in the French Civil War, is most effectively formulated as a 1–2% iodine solution in 70% ethyl alcohol. In this form, most (approximately 90%) bacteria are killed within 3 minutes of application. The antibacterial activity of this combination is greater than that of the alcohol alone. Tincture of iodine, however, is irritating and allergenic, corrodes metals, and stains skin and clothing. It is also painful when applied to open wounds and is harmful to host tissue; therefore, it can delay healing and increase the chance of infection. For these reasons, this preparation has fallen out of favor as an antiseptic or disinfectant. Strong tinctures of iodine have been used as blistering agents in the equine industry.

Efforts to reduce the undesirable aspects of tinctures while retaining the powerful killing action of iodine have led to the introduction of tamed iodines known as iodophors. In this preparation, iodine is solubilized by surfactants, which allow it to remain in a dissociable form. Application of this product allows for slow continual release of free iodine to exert its germicidal effects. The iodophors have a similar spectrum of activity to aqueous solution; are less irritating, allergenic, corrosive, and staining; and have prolonged activity after application (4–6 hours). Common solubilizing carriers include polyvinylpyrrolidone (called PVP-iodine or povidone-iodine, PI) as well as other nonionic surfactants, making iodophors excellent cleansing agents as well as antiseptics and disinfectants. Iodophor solutions retain their activity in the presence of organic matter at pH <4 (Huber, 1988). The water-soluble carriers have been postulated to interact with epithelial surfaces to increase tissue permeability, thereby enhancing iodine's killing efficacy.

Proper dilution to 1% iodine is necessary for maximum killing effect and minimal toxicity. More-concentrated solutions are actually less efficacious, presumably due to stronger complexation preventing free iodine release. It takes approximately 2 minutes of contact time for release of free iodine (Lavelle et al., 1975). Literature reports indicate that iodophors are quickly bactericidal, virucidal, and mycobactericidal but may require prolonged contact times to kill certain fungi and bacterial spores. Iodophors formulated as antiseptics are not suitable as hard-surface disinfectants, due to insufficient concentrations of iodine.

Consideration must be taken of iodine's ability to be systemically absorbed through the skin and mucous membranes. The extent of absorption is related to the concentration used, frequency of application, and status of renal function (the principal excretory route) (Swaim and Lee, 1987). Complications of iodophor absorption include increased serum enzyme levels, renal failure, metabolic acidosis (Pretsch and Meakins, 1976), and increased serum free iodide. If renal function is normal, serum iodine concentrations quickly return to normal. Clinical hyperthyroidism and thyroid hyperplasia have been reported after treatment with PI (Scheider et al., 1976; Altemeier, 1976).

Chlorine-containing solutions were first introduced by Dakin in the early 1900s in the chemical form of sodium hypochlorite. They are effective bactericidal, fungicidal, virucidal, and protozoacidal agents. The chemical forms most commonly used today include the hypochlorites (sodium and calcium) and organic chlorides (chloramine-T). In either form, the germicidal activity is due to release of free chlorine and formation of hypochlorous acid (HOCl) from water. The mechanisms of action of these compounds include inhibition of cellular enzymatic reactions, protein denaturation, and inactivation of nucleic acids (Dychdala, 1983). Dissociation of HOCl to the less microbicidal hypochlorite ion (OCl^-) increases as pH increases, and thus the solution may be rendered ineffective above pH 8.0 (Weber, 1950). Mixing NaOCl with acid liberates toxic chlorine gas, and NaOCl decomposes when exposed to light.

Low concentrations of free chlorine are active against M. tuberculosis (50 ppm) and vegetative bacteria (<1 ppm) within seconds. Concentrations of 100 ppm destroy fungi in less than 1 hour, and many viruses are inactivated in 10 minutes at 200 ppm. Household bleach is 5.25% (52,500 ppm); thus dilutions of 1 : 100 to 1 : 250 should result in effective germicidal concentrations although more-concentrated solutions are often recommended (1 : 10 to 1 : 100).

The use of the hypochlorites as disinfectants are limited by several characteristics. Chlorine solutions are corrosive to metals and destroy many fabrics. Because chlorine solutions are unstable to light, they must be prepared fresh daily. Hypochlorites are inactivated by the presence of blood more so than are the organic chlorides (Bloomfield and Miller, 1989). They have a strong odor and are not suitable for enclosed spaces. In addition, hypochlorites may lead to irritation of mucous membranes and may form toxic bioproducts when interacting with other chemicals. Despite these shortcomings, chlorine solutions are commonly used as low-level disinfectants on dairy equipment, animal housing quarters, hospital floors, and other noncritical items. Of 12 disinfectant solutions evaluated for their ability to kill the dermatophyte *Microsporum canis*, those containing hypochlorite were most effective. Also found effective were benzalkonium chloride and glutaraldehyde-based products; phenolics and anionic detergents were considered inadequate (Rycroft and McLay, 1991). The hypochlorites are not recommended for routine use as antiseptics because they are very irritating to skin and other tissues and they delay healing. There is, however, research to suggest diluted household bleach can be applied to control superficial pyoderma in dogs.

Several compounds from a class called N-halamines (oxazolidinones or imidazolidinones) have been developed, which are water-soluble solids that have been shown to be bactericidal, fungicidal, virucidal, and protozoacidal in water disinfection at low total halogen concentrations (1–10 mg/l). They are noncorrosive and tasteless and odorless in water. They are extremely stable in water even in the presence of organic loads. Their potential use in poultry processing to control *Salmonella* has been evaluated (Smith et al., 1990).

Biguanides

Chlorhexidine (Chx) is popular synthetic cationic antiseptic compound (1-1’-hexamethylenebis[5-(p-chlorophenyl)biguanide]) with better activity against gram-positive than against gram-negative organisms. The compound lacks sporicidal activity. Chlorhexidine kills bacteria by disrupting the cell membrane and precipitating cell contents. It has also been suggested that membrane-bound adenosine triphosphatases, specifically inhibition of the F1 ATPase, may be a primary target for Chx (Gale et al., 1981). It is active against fungi, fairly active against *M. tuberculosis*, but poorly active against viruses. The antibacterial activity of Chx is not as rapid as that of the alcohols; however, as a 0.1% aqueous solution, significant killing action is evident after only 15 seconds. Additionally, Chx solutions have the longest residual activity, remaining chemically active for 5–6 hours and retaining their activity in the presence of blood and other organic material. Being cationic, it is inactivated by hard water, nonionic surfactants, inorganic anions, and soaps. Dilution with saline causes precipitation and its activity is pH dependent. It has extremely low toxicity even when used on intact skin of newborns (O’Neill et al., 1982). Chlorhexidine is available in a detergent base as a 4% solution or as a 2% liquid foam. Traditionally, it has widely been used as a presurgical antiseptic, wound flush, and teat dip. Formulations of chlorhexidine and alcohol have also been described and appear to improve efficacy. Its use as a disinfectant are not well described.

Polyhexamethylene biguanide (PHMB) is a polymeric biguanide with activity against gram-positive and gram-negative bacteria, including methicillin-resistant *Staphylococcus aureus*, *Pseudomonas aeruginosa*, and *Streptococcus equi*. PHMB rapidly kills bacteria by disrupting the cytoplasmic membrane resulting in leakage and precipitation of cellular contents (Broxton et al., 1983). PHMB has been used to treat infections in the eye, mouth, and vagina and has been formulated in contact lens disinfectants and mouth rinses. It was shown to be nontoxic as a component of an ear flush for dogs (Mills et al., 2005) and when impregnated in a gauze wound dressing, reduced growth of underlying gram-positive and gram-negative bacteria in vitro (Lee et al., 2004).

Aldehydes

Two related aldehyde disinfectants are formaldehyde and glutaraldehyde (GLT). Formaldehyde has antimicrobial activity both as a gas and in liquid form. Formalin, the aqueous form, is 37% formaldehyde by weight. It inactivates microorganisms by alkylating the amino and sulfhydryl groups of proteins and ring nitrogen atoms of purine bases (Favero, 1983). Formaldehyde is an effective but slow bactericide, virucide, and fungicide, requiring 6–12 hours contact time. It is effective against *M. tuberculosis*, bacterial spores, and most animal viruses, including foot-and-mouth disease virus. Its action is not affected by organic matter and it is relatively noncorrosive to metals, paint, and fabric. Formaldehyde alone is considered a high-level disinfectant and in combination with alcohol can be used as a chemical sterilant for surgical instruments. However, due to irritating fumes and pungent odor at low concentrations (approximately 1 ppm), and because the National Institute for Occupational Safety and Health requires it to be handled as a potential carcinogen, thereby limiting worker exposure time, formaldehyde's use as a disinfectant has been limited.

Glutaraldehyde, a saturated dialdehyde, is similar to formaldehyde but without some of its shortcomings. It has better bactericidal, virucidal, and sporicidal activity than formaldehyde. Its biocidal activity is related to its ability to alkylate sulfhydryl, hydroxyl, carboxyl, and amino groups affecting RNA, DNA, and protein synthesis (Scott and Gorman, 1983). Acidic GLT solutions are not sporicidal; thus, they must be "activated" by alkalinizing agents to a pH between 7.5 and 8.5. Once activated, these solutions have a limited shelf life (14 days) due to polymerization of the GLT molecules (Rutala, 1990). Newer formulations (stabilized alkaline GLT, potentiated acid GLT, GLT-phenate) have increased shelf life (28–30 days) and excellent germicidal activity (Pepper, 1980). GLT has gained wide acceptance in high-level disinfection and chemical sterilization due to several favorable properties, including wide spectrum of activity. Low surface tension allows GLT to penetrate blood and exudate without coagulating proteins. It retains its biocidal activity in the presence of organic matter. It is noncorrosive to metal, rubber, and plastic and does not damage lensed instruments. GLT solutions must be used in well-ventilated areas, since air concentrations of 0.2 ppm are irritating to the eyes and nasal passages (CDC, 1987). Contact times of less than 2 minutes for vegetative bacteria, 10 minutes for fungi, and 3 hours for bacterial spores were necessary using a 2% aqueous alkaline GLT solution (Stonehill et al., 1963). Activity against the tubercle bacillus was found to be somewhat variable; at least 20 minutes at room temperature is needed to reliably kill these organisms with 2% GLT. When used as a high-level disinfectant, a minimum of 1% GLT should be used. GLT-phenate formulations should be used with caution since they were shown to be less effective than other aldehyde solutions in decreasing bacterial counts from some medical instruments (Ayliffe et al., 1986). GLT disinfectants were found to more effectively reduce duck hepatitis B virus infectivity when they contained additives such as alcohol, an ammonium chloride derivative, and a surfactant (Murray et al., 1991). The caustic nature of both formaldehyde and GLT makes them inappropriate as antiseptics, and in fact, protective gloves should be worn when using the aldehyde disinfectants.

Gluteraldehyde and QAC combinations have been formulated (e.g., Synergize^{TM}, Preserve International, Reno, NV) and largely marketed as a cleaner and disinfectant for use in animal (e.g., swine and poultry) production facilities.

Oxidizing Compounds

Conflicting reports concerning hydrogen peroxide's efficacy as a germicide make evaluating its utility in disinfection and antisepsis difficult. Although it has been reported to have bactericidal (Schaeffer et al., 1980), virucidal (Mentel and Schmidt, 1973), and fungicidal (Turner, 1983) activity, the activity of hydrogen peroxide is nonpenetrable and short lived. For this reason hydrogen peroxide antiseptic use is most valuable in the initial treatment of recently contaminated wounds. Because 3% hydrogen peroxide has been shown to be damaging to tissues, including fibroblasts (Lineweaver et al., 1982), it is not considered suitable for routine wound care. It is, however, considered a stable and effective disinfectant and is used in the disinfection of soft contact lenses. More recently, accelerated hydrogen peroxide products have been formulated to also contain a surfactant and stabilizer, which improve antimicrobial activity. These products are being implemented in many veterinary clinic settings for use as a disinfectant.

Other oxidizing agents include potassium peroxymonosulfate (PPMS), an oxidizing agent used in disinfection systems of pools and hot tubs. More recently, it has been formulated with potassium chloride and organic acids and salts (i.e., sulphamic acid, malic acid, sodium hexametaphosphate, and sodium dodecyl benzene sulphonate) resulting in a disinfectant effective against over 580 infectious agents including viruses, gram-positive and gram-negative bacteria, fungi (molds and yeasts), and mycoplasma (EPA Master Label). It is marketed as a powder because it is stable in solution for approximately 1 week. It is not inactivated by organic challenge and has been found to be user friendly to both humans and animals. It is widely used as a high-level disinfectant for surfaces in laboratories, dental care facilities, and hospitals; for decontaminating laundry; for air disinfection; and in food processing and transport. Use of peracetic acid, sodium perborate, benzyl peroxide, and potassium permanganate have also been reported in human and veterinary literature.

Phenols

Carbolic acid, a phenol, is the oldest example of an antiseptic compound. However, due to severe toxicity, it is no longer appropriate for use as an antiseptic. These agents act as cytoplasmic poisons by penetrating and disrupting microbial cell walls. Most commercially available phenolic products contain two or more compounds that act synergistically, resulting in a wider spectrum of activity, including against *M. tuberculosis*. Sodium o-phenylphenol is effective against staphylococci, pseudomonads, mycobacteria, fungi, and lipophilic viruses, and against ascarids, strongyles, and tichurids. Cresols are substituted phenols and are more bactericidal and less toxic and caustic than phenols. Phenolics are not recommended for disinfection of anything other than noncritical items, because of residual disinfectant on porous materials causing tissue irritation even when the items have been thoroughly rinsed, because of strong odors, and because of absorption into feed.

Triclosan (Irgasan DP 300; 2,4,4′ trichloro-2′-hydroxydiphenyl ether) is a chlorinated diphenyl ether or bisphenol that possesses high antibacterial activity particularly against many gram-positive (e.g., *Bacillus subtilis*, *Mycobacterium smegmatis*, *Staphylococcus aureus*) and gram-negative bacteria (*Escherichia coli*, *Salmonella enterica* serotype Typhimurium, *Shigella flexneri*) as well as fungi and yeasts (Stewart et al., 1999). Triclosan has been used for over 30 years and was first introduced in the health care industry in a surgical scrub in 1972. However, recently there has been a rapid increase in the use of triclosan-containing products including soaps, disinfectants, deodorants, shampoos, and medical supplies. In addition, it can be incorporated into plastics (e.g., children's toys) and fibers to retard decomposition.

The mechanisms of action of triclosan have been debated, but it is likely that they are concentration dependent. At low concentrations, triclosan acts as a competitive inhibitor of bacterial enoyl-acyl carrier protein reductase, which is involved in the bacterial fatty acid elongation cycle. At higher concentrations, because of its lipophilicity, triclosan has been shown to incorporate into bacterial membranes to alter the physicochemical properties of the lipid bilayer, including perturbation of the packing and interaction between membrane phospholipids (Guillen et al., 2004). Resistance due to specific mutations (Heath et al., 1999) of the bacterial carrier protein has been demonstrated in *S. aureus* and *E. coli* (Fan et al., 2002). The clinical significance of this decreased sensitivity remains questionable since concentrations achieved during triclosan use are likely high enough for the generalized bactericidal activity to prevail. Decreased sensitivity has been demonstrated in bacteria that overexpress the AcrAB efflux pump (Wang et al., 2001). The possibility and data suggesting that these resistance mechanisms may not only confer resistance to triclosan but also to other antibiotics has led to concern about the ubiquitous use of this compound in detergents, toothpaste, and other household items.

Gases

Technologies using ethylene oxide or hydrogen peroxide gas plasma for sterilization have been described. These products may be toxic and are not appropriate for antisepsis but could be useful in the treatment of temperature-sensitive medical devices or equipment. Ethylene oxide (C_2H_4O) is a water-soluble flammable gas. Mixing ethylene oxide with carbon dioxide or fluorocarbons reduce its flammability. Ethylene oxide kills bacteria, fungi, yeasts, viruses, and spores. Bacterial spores are only two to ten times more resistant to the cidal activity than are vegetative cells. It has been shown that the relative humidity of the microenvironment is critical to microbial susceptibility to ethylene oxide. Activity is decreased in the presence of organic matter due to interaction with proteins and nucleic acids. Care must be used to contain the gas as it has an irritant effect on the skin and eyes and may cause headaches and nausea. Hydrogen peroxide gas plasma has also been reported to have efficacy against a broad range of microorganisms, including bacterial spores.

Formaldehyde gas inactivates viruses, fungi, bacteria, and bacterial spores. Its activity is dependent on relative humidity and its efficacy is thought to peak at less than 50% relative humidity. Formaldehyde has been used for disinfection of hospital linen and for terminal disinfection in certain food-producing industries (see Section *Salmonella*). Propriolactone, methyl bromide, and propylene oxide have also been used as gas disinfectants.

Factors Affecting Efficacy of Antiseptics and Disinfectants

As indicated above, many factors can influence the efficacy of antiseptics and disinfectants. Often, more than one of these factors is contributing to the efficacy of an antiseptic or disinfecting product in a clinical setting.

Concentration

In general, the time needed to kill an organism is inversely dependent upon antimicrobial concentration; however, for certain compounds a small decreases in concentration may result in large increases required for killing whereas other compounds are less sensitive to changes in concentration. Alcohols and phenolics are very concentration dependent, whereas QACs, aldehydes, and chlorhexidine are less sensitive.

Table 31.1 Q_{10} coefficients for selected disinfectant/antiseptic compounds

Compound	Q_{10} Coefficient
Formaldehyde	1.5
β-propriolactone	2–3
Ethylene oxide	2.7
Phenol and cresol	3–5
Aliphatic alcohols	30–40

Exposure Time

A minimum contact time is required for efficacy of most antiseptics and disinfectants. All registered EPA disinfectants are labeled with an appropriate contact time. Reducing the exposure time below recommended times could lead to incomplete germicide activity.

Temperature

Increased temperature results in increased antimicrobial activity. This relationship can be described by $Q_{(T2-T1)}$ = (time to kill at T_1) / (time to kill at T_2), where T_2 and T_1 are two different temperatures in centigrade degrees. This equation is commonly referred to as the Q_{10} coefficient and describes the change in activity caused by a 10°C rise in temperature. Table 31.1 lists the Q_{10} coefficient for certain disinfectant compounds.

pH

The pH at the site of action may affect a compound's activity by two mechanisms, influencing the compound or the microbial cell. Molecules such as phenols, and certain acids, including hypochlorous acid (bleach), are effective only in the unionized form, thus as pH increases they become less efficacious. Glutaraldehyde is more potent at alkaline pH but is more stable at acid pH. Increased pH results in higher numbers of negative charges on cell surfaces with which positively charged molecules, such as QACs and chlorhexidine, can interact, thereby increasing their activity. Lastly, in a process similar to absorption through any cell membrane, pH can effect partitioning from the bathing solution into the cell's interior.

Contamination

The most important step to maximize antiseptic or disinfectant efficacy is thorough cleaning and washing of the site or area prior to application. Organic matter such as blood, pus, feces, soil, food, and milk, are believed to directly reduce the activity of antimicrobial compounds via a chemical reaction which results in a smaller amount of compound available for killing microorganisms or by spatial nonreaction (the inability of the disinfectant molecule to get to the organism). Certain compounds (hypochlorites and iodines) are more susceptible to this type of interference than others. Glutaraldehyde is less affected by organic contamination than other compounds and is therefore useful for instruments whose surface or design make it impossible to thoroughly clean. In a veterinary setting, contamination can make disinfection of large animal facilities difficult and may require removal of surface layers of soil and bedding for complete treatment. The presence of inorganic ions, Ca^{+2}, Mg^{+2}, Na^{+}, and Cl^{-} may be physically incompatible with certain antiseptics/disinfectants and therefore dilution with either hard water or saline solutions may render these formulations ineffective.

Organism Type

The sensitivity of different organism types (bacteria, virus, fungi, and spores) have been previously discussed for levels and types of disinfecting agents. Within an organism type, differences between genera and species also exist, which may render a particular disinfection process ineffective against certain microbes yet effective against others. Gram-positive bacteria are in general less resistant to disinfectant and antiseptic compounds than are gram-negative organisms due to a less complex and less lipid-rich cell wall. Staphylococci are less susceptible to alcohols, glycols, and ethylene oxide than are other cocci. Of the gram-negative bacteria, *Pseudomonas aeruginosa* have been identified as more resistant to antimicrobial agents, especially QACs, than other species. Mycobacteria, due to the unusual and hydrophobic nature of their cell wall, are highly resistant to many compounds. Bacterial sporicides include the aldehydes, hydrogen peroxide, hypochlorites, iodine, acid alcohol, and ethylene oxide. By inhibiting germination or spore outgrowth, phenols, QACs, biguanides, and alcohols are sporostatic. The efficacy of most germicides against bacterial spores increases with temperature; however, the most effective method against bacterial spores is moist heat (115°C autoclaving). Fungi are sensitive to chlorine, phenols, iodine compounds, ethylene oxide, and the aldehydes, whereas QAC are fungistatic. Fungal spores are resistant to most disinfectants. The sensitivity of viruses to disinfectant compounds relates to the composition of the viral envelope. The lipid-enveloped viruses are readily inactivated by lipophilic agents such as ether, chloroform, phenols, QACs, and even detergents. The nonenveloped viruses are resistant to these agents but are sensitive to chlorine and the aldehydes. Formaldehyde and β-propriolactone are used to inactivate viruses in the production of viral vaccines utilized in veterinary medicine.

Formation of Biofilms

Bacteria present on metal or other surfaces may form a biofilm (Mafu et al., 1990) that is an adherent slimy layer consisting of an organic polymer matrix in which microbes are embedded. In addition, the intercellular matrix contains products of cellular metabolism including ions, nutrients, and enzymes such as polysaccharases, proteases, and β-lactamases. Differing cellular densities and extracellular concentrations of factors results in diverse cellular phenotypes with regard to growth rate, nutrient deprivation, etc. Bacteria in biofilm are less sensitive to disinfectant inactivation than are those grown in culture broth (i.e., planktonic). Proposed reasons for this increased resistance include decreased diffusion of disinfectant solution through polymer matrix preventing centrally located cells from being exposed to lethal concentrations of the compound. Chemical or enzymatic modification by extracellular components or decreased inherent microbe susceptibility due to slow growth rate or starvation responses may also contribute to increased bacterial survival in biofilms (Gilbert et al., 2002).

Resistance to Antiseptics and Disinfectants

Similar to resistance towards traditional antibiotics, bacteria can acquire genes that are associated with resistance toward antiseptic and disinfectant compounds. In general, acquisition of a genetic element (e.g., plasmid, transposon) or a chromosomal mutation results in bacteria with reduced susceptibility or increased tolerance; acquired resistance may not mean failure of an antiseptic or disinfectant, however. Concentrations of disinfectants in practice are generally much higher than the cidal concentration required to kill bacteria in vitro.

Staphylococcus aureus has been shown to be resistant to triclosan, quaternary ammonia compounds, and chlorhexidine (Heath and Rock, 2000; Suller and Russell, 1999, 2000). There are also reports of low-level resistance to QACs and chlorhexidine in *Pseudomonas* species (Mechin et al., 1999; Bamber and Neal, 1999; Tattawasart et al., 1999). However, this resistance has been considered unstable and not clinically significant (Russell, 2000). The possibility that the mechanisms of resistance developed against a disinfectant or antiseptic could confer resistance to an antibiotic, however, is considered quite possible and potentially clinically disastrous. It may also be possible that resistance genes associated with disinfecting or antiseptic agents are located on the same genetic element as genes encoding for antibiotic resistance.

The mechanisms of action of antibiotics are well known and in most cases, take advantage of a single specific target (e.g., inhibitors of peptidoglycan, protein, and nucleic acid synthesis, inhibitors of RNA polymerase, DNA gyrase) in their ability to kill or suppress the growth of bacteria. This is in contrast to mechanisms of action of disinfectants and antiseptics, which are less well understood and often involve more general and multiple cellular targets (Denyer and Stewart, 1998). These include interactions with the cell wall or the envelope, disruption of membrane integrity, interruption of the proton-motive force, and inhibition of membrane enzymes, or as alkylating, cross-linking, and intercalating agents. Similarly, the mechanisms of resistance to antibiotics have been better characterized than those to biocides. Changes in the drug's target (e.g., methylation of the ribosome, penicillin-binding protein alterations), impermeability to the drug (e.g., intrinsic gram-negative resistance, biofilm formation), enzymatic modification or destruction of the drug (e.g., β-lactamases), and increased efflux of the drug can confer resistance to antibiotics.

As mentioned, there is evidence of resistance to disinfectants developing or being measured in vitro; however, because of redundancy in the number of targets for activity and the ability to achieve very high concentrations of biocide chemicals at the site of contamination, in vivo or clinical resistance to these compounds is not thought to be prevalent. However, because several of the mechanisms that allow for this resistance are common to those that provide resistance to antibiotics (efflux, impermeability, modification of target sites), the possibility for decreased efficacy to antibiotics is real.

β-lactam resistance in association with resistance to quaternary ammonia compounds has been demonstrated in *S. aureus* (Akimitsu et al., 1999). Triclosan-resistant mycobacteria were also resistant to isoniazid (McMurry et al., 1999), and there are many reports of biocide–antibiotic cross resistance in gram-negative bacteria. For example, *E. coli* that are resistant to triclosan (McMurry et al., 1998) or pine oil (Moken et al., 1997) have been shown to display the multiple antibiotic resistance (mar) phenotype. It is generally believed that in *E. coli* the mar phenotype is attributable to increased efflux due to up-regulation of the efflux pump (e.g., AcrAB-ToIC) (Okusu et al., 1996), which can cause resistance to β-lactams, chloramphenicol, fluoroquinolones, and tetracyclines.

The discovery of ciprofloxacin-resistant *E. coli* on farms with no previously reported quinolone exposure suggests that a disinfectant caused antibiotic resistance (Randall et al., 2005). Based on laboratory investigations designed to induce antibiotic resistance by repeated exposure to three different disinfectants, these authors conclude that, although bacteria became less sensitive to fluoroquinolones, this mechanism could not produce clinically resistant strains from fully susceptible ones.

They further conclude that the risk of disinfectant exposure giving rise to multiple antibiotic resistant bacteria is outweighed by the value of sanitation provided by these compounds.

Examples of Antiseptic Use in Veterinary Medicine

Several resources, including the Centers for Disease Control and Prevention and World Health Organization, outline the role of antiseptics and disinfectants in human health care settings; many of the principals discussed in those references could be applied to veterinary hospitals. Discussions and research on antiseptic and disinfectant practices specific to veterinary medical settings are on-going and recommendations are expected to become more refined. Below are several specific examples of the role of antiseptics and disinfectants in veterinary medicine.

Presurgical Skin Cleansers

Skin cleansers are important in the presurgical antisepsis of both the surgeon and the patient. Historically, the recommendations for presurgical antisepsis of the surgeon include two alternatives. The first involves an initial water-and-soap cleansing followed by use of an alcohol-based rub for at least 5 minutes. The second and more traditional method consists of a 5-minute chlorhexidine or iodophor hand scrub. Alcohol hand rubs are effective in immediately eliminating pathological bacteria on the hand skin surface and have a prolonged period of action superior to traditional antiseptics. Chlorhexidine techniques have the advantage that the active agents have residual bactericidal activity under surgical gloves; however, they have been shown to have negative effects on the skin of health care workers, resulting in tissue disruption, elimination of beneficial deeper microflora, and predisposition to colonization with pathogenic bacteria. For this reason, the World Health Organization (WHO) now recommends alcohol-based handrubs as the gold standard (WHO, 2009). The presence of organic material and dirt can decrease the effectiveness of most antiseptics; thus removal of gross contamination should precede any antiseptic scrub. Additionally, an important reservoir of dirt and bacteria that needs to be specifically addressed is the subungual space (McHinley et al., 1988).

Preoperative preparation of the veterinary patient varies depending on the surgical environment, yet attempts to achieve the optimal antiseptic cleansing can aid in limiting postsurgical infections. Contrary to human surgery, hair removal from the operative site is almost always a necessity with animal patients. Clipping hair is superior to shaving since it causes less damage and less favorable conditions for bacterial colonization of the surgical skin site (Alexander et al., 1983). Removal of gross contamination and dirt should precede use of antiseptics for previously mentioned reasons. Gentle antiseptic scrubbing should begin at the incision site and move outward over the entire surgical area. Consideration of proper antiseptic contact times should be made. A final antiseptic spray is often applied and left to dry on the surgical site. Despite even the most careful presurgical preparation, up to 20% of skin-resident bacteria may be unaffected by skin antiseptic cleansing (Smeak and Olmstead, 1984). Characteristics of an ideal skin antiseptic include broad spectrum, rapid killing, persistent lethal effect, cleansing effect, lack of skin irritation, noninhibition of healing, and activity in the presence of organic material.

In one study, three antiseptic combinations were evaluated for surgical preparation of canine paws (Swaim et al., 1991): 7.5% PI scrub/10% PI solution, 2% Chx acetate scrub/2% Chx diacetate solution, and tincture of green soap/70% isopropyl alcohol combinations were each shown to effectively reduce bacterial colony counts. The first two combinations were also effective in residual killing when applied under a sterile bandage for 24 hours. However, no significant advantage of applying the antiseptics 24 hours prior to surgery was shown. This is in contrast to results in human patients, where antiseptic cleaning the night prior to surgery has resulted in fewer wound infections (Garibaldi et al., 1988). A similar technique involving prophylactic antiseptic cleansing and wrapping of a limb overnight has been shown to reduce contamination of equine orthopedic surgical sites (Stewart, 1984). For surgery of the foot, additional reduction in bacteria load was achieved by removal of the superficial layer of the hoof; however, counts remained above a level that might predispose the surgical site to infection (Hennig et al., 2001). Antibacterial agents found in shampoos were shown to prevent infections caused by *S. intermedius* in a skin infection model in beagles. Shampoo containing 3% benzoyl peroxide was most effective, followed by shampoos containing 0.5% Chx acetate and iodine (1.0% polyalkyleneglycol-iodine) (Kwochka and Kowalski, 1991).

Another study compared the presurgical efficacy of chlorhexidine to a stabilized glutaraldehyde compound. Glutaraldehyde is most commonly associated with disinfection of inanimate objects; however, in its stabilized form it was noncorrosive, nonvolatile, nontoxic, biodegradable, stable, and highly microbiocidal at neutral pH. Stabilized glutaraldehyde, with and without alcohol, and chlorhexidine with alcohol had similar and significant ability to reduce and maintain surface bacteria levels and therefore were recommended for presurgical antiseptic prophylaxis in elective (noncontaminated) procedures (Lambrechts et al., 2004).

Treatment of Open Wounds

The treatment of open wounds is an important procedure in veterinary medicine. The processes involved in wound healing and proper wound care have been reviewed (Swaim and Wihalf, 1985; Berk et al., 1992). Issues involved in the decision of how to properly treat a wound include patient age and general health status, and the age, cause, size, and extent of contamination of the wound. Treatment options include surgical closure, bandaging (of different types), and irrigation or application of a varied group of topical agents, including saline, antiseptics, antibiotics, and local anesthetics. It is important to recognize that each wound has different characteristics and thus treatment must be individualized. For all wounds, however, a basic principle to which all caregivers should adhere is "above all, do no harm"; that is, any agent chosen should not impede the healing process. When treating a wound topically, a general guideline would be not to apply anything that should not be placed in the patient's conjunctival sac (Peacock, 1984).

The literature is divided concerning the utility of antiseptics in routine wound care. Some authors contend that this practice reduces the incidence of infections as a complication (Zukin and Simon, 1987), while others believe that any benefit is outweighed by the potential for these agents to cause tissue damage (Oberg and Lindsey, 1987). Once the healing process has begun, however, the use of more-benign agents may be indicated. Saline has been shown to be an effective means of eliminating debris and lowering bacterial counts (Stevenson et al., 1976). Hypertonic saline has also been proposed as a wound dressing (Lowthian and Oke, 1993). Archer et al. (1990) report that surface colonization of wounds does not impede healing and thus recommend a move away from potentially damaging antiseptics.

Many reports in the literature discuss potential toxic and harmful effects of antiseptics on fragile healing tissues, making their use controversial. A 5% PI solution inhibited local leukocyte migration, fibroblast activity, and wound cellularity (Viljanto, 1980). In vitro, neutrophil migration was inhibited at concentrations greater than 0.05% (Tvedten and Till, 1985), whereas 1% PI killed fibroblasts and resulted in weaker wound breaking strength (Lineweaver et al., 1985). Detergent scrubs containing PI and other surfactants were found to damage wound tissue and therefore are not recommended for wound care (Rodheaver et al., 1982). A maximum of 1% PI solution has been recommended as the most effective and least tissue-toxic dilution for wound irrigation (Swaim and Lee, 1987). Because antibacterial activity lasts 4–6 hours, repeated treatment is necessary for optimal results.

Chlorhexidine's residual activity (possibly by binding to proteins of the stratum corneum) and its activity against many organisms, make it a useful wound treatment. In an experimental wound infection model, wounds irrigated with 0.05–1% Chx diacetate solution had fewer infections than those treated with 0.1–0.5% PI. Concentrations of Chx gluconate 0.5% or greater were effective against *S. aureus* in vitro; however, concentrations above 0.05% were lethal to equine fibroblasts (Redding and Booth, 1991) and in a wound model in pigs. Unfortunately, it also delayed healing to a greater extent than other solutions tested, including PI (Archer et al., 1990).

Chlorine solution, such as sodium hypochlorite, was used as an effective wound flush in World War I. Full strength Dakin's solution (0.5% NaOCl) kills bacteria and fibroblasts, as well as retarding epithelialization in vivo in rats (Lineweaver et al., 1985). Other studies have shown low concentrations (0.025–0.0025%) to be toxic to neutrophils, fibroblasts, and endothelial cells, prompting one author to recommend abandoning the use of NaOCl as an irrigant (Kozol et al., 1988). In contrast, a concentration of 0.025% NaOCl was shown to be bactericidal while having no in vitro or in vivo tissue toxicity, suggesting a modified Dakin's solution may be a safe and effective fluid dressing (Heggers et al., 1991). Chloramine-T (Chlorazene) was shown to reduce in vitro *Pseudomonas aeruginosa* growth and the ability of the bacteria to colonize experimentally created wounds in guinea pigs. Additionally, Chlorazene was seen not to delay the healing of these wounds at a concentration of 0.03% (Henderson et al., 1989). Thus, it was concluded that this preparation should have no effect on healing of wounds when used to sanitize hydrotherapy units. More recently, sodium hypochlorite solutions have been proposed and evaluated for treatment of atopic dermatitis and recurrent pyoderma in dogs, as it is highly effective against *Staphylococcus* species in vitro. The use of this and other topical antiseptic products is being increasingly investigated as veterinarians continue to struggle with antibiotic resistant (including methicillin-resistant *Staphylococcus* spp.) organisms associated with skin infections.

Examples of Disinfectant Use in Veterinary Medicine

Disinfectants are widely used in veterinary medicine on floors, tables, walls, surgical equipment and other instruments before storage, and for disinfection of animal housing facilities. For effective germicidal activity, manufacturer recommendations regarding contact time, dilution, and useful life of a disinfectant solution should be followed. The best disinfectant for a particular situation will depend on the surface's shape, structure, chemical reactivity, and use, as well as on the type of contaminating organisms anticipated. In addition, in almost all instances, disinfection is only effective after the removal and cleaning of organic debris.

Although detailed descriptions of guidelines for disinfectant use in all circumstances is beyond the scope of this chapter, it is justified to provide several examples of their use in situations involving microbes that cause significant health concerns or that can be easily transmitted.

Salmonella

Salmonella species are well known by veterinarians and controlling transmission of the organism is important in a variety of settings. There are many *Salmonella* serotypes, some of which may be associated with an increased concern for transmission. An important food-borne pathogen, control of *Salmonella* on production animal facilities, even when animals are asymptomatically shedding the organism in feces, is important for public health and consumer confidence. Zoonotic transmission in a veterinary clinic setting from a cat to technical staff has also been reported (Cherry et al., 2004). In other situations, patients are symptomatic with a *Salmonella* infection and efforts to prevent transmission to other patients, particularly in hospital or boarding facilities, is critical. Several highly publicized *Salmonella* outbreaks have caused interruptions in services at veterinary teaching hospitals, prompting the search for effective methods of detection, prevention, and disinfection. Environmental contamination (Patterson et al., 2005) or affected individuals (Schott et al., 2001) may have been the initiating events; however, housing of sick and immunocompromised patients as well as incomplete disinfection likely contributed to routine shedding developing into epidemics. Sites and methods of sampling for monitoring for *Salmonella* contamination have been proposed and a high frequency of positive results have been recorded (~50%). However, this high percentage may reflect the sampling and detection method and not necessarily disease risk. The ability to decontaminate a veterinary hospital quickly, efficiently, and effectively is paramount to preventing loss of income and public confidence and to ensuring high quality treatment of the veterinary population. Following one outbreak (in 1996 at Colorado State Veterinary Teaching Hospital) the facility was at least partially closed for 3 months to allow manual decontamination/disinfection.

Disinfectant footbaths have been used as a hygiene barrier to prevent spread of microbes in veterinary hospital environments. Footbath efficacy has been shown to be dependent upon the disinfectant used and the compliance with which it is utilized. In one study, a peroxygen compound was shown to be more effective than a QAC; however, a maximal reduction in contamination of only 75% was observed (Morley et al., 2005). These results suggest that footwear hygiene can be improved through appropriate use of disinfectant footbaths, but it should not be relied on as the only method of controlling the spread of infectious agents. Mist application of a 4% peroxymonosulfate compound was shown to be an effective method of eliminating artificially induced contamination of an animal holding facility (Patterson et al., 2005).

Glutaraldehyde was found to be the most effective compound in reducing *Salmonella enteritidis* and *S. senftenberg* bacterial load in a study designed to mimic worst-case conditions in disinfecting poultry houses (Gradel et al., 2004). Four types of materials (e.g., concrete, wood) were contaminated with bacteria mixed with several types of organic matter (e.g., feed, egg yolk) and disinfection was attempted at high and low temperatures. Formaldehyde was considered effective even at low temperatures despite reports that a minimum temperature of 16°C is required for activity, whereas a peroxygen compound was found to be least effective except for one material/organic matter combination. This lack of efficacy was attributed to peroxygen compounds inactivation in the presence of organic matter.

In a similar study that investigated disinfection of poultry transport containers, real-world conditions were created by testing five compounds against bacteria growing isolated and in a biofilm. Although halogen compounds and QAC were effective against artificially contaminated surfaces, after the biofilm had matured, only sodium hypochlorite or an iodine-containing disinfectant was able to achieve 100% reduction. In the ultimate test of disinfectant activity in the face of organic matter, sodium carbonate, ammonia, and sodium hydroxide were shown to reduce food-borne pathogen load in cattle manure (Park and Diez-Gonzalez, 2003).

Avian Influenza

The spread of avian influenza (including highly pathogenic avian influenza, HPAI) among poultry populations and is very concerning and problematic. As an enveloped virus, the orthomyxoviridae, including influenza viruses, are very sensitive to most detergents and disinfectants. They are readily inactivated by pH, heating, and drying. The US Environmental Protection Agency currently reports approximately 200 products registered for disinfection use against avian influenza. These products are typically intended to be used by poultry producers to disinfect their facilities after an outbreak. Classes of disinfectants considered effective at destroying avian influenza virus include alcohols, phenolics, oxidizing agents, and dilute acids. However, flu viruses are well protected from inactivation by organic material, and infectious virus can be recovered from manure for up to 105 days. It is therefore suggested that complete removal of all organic material is part of any effective disinfection procedure. Contaminated litter and manure should be composted or buried to ensure that it does not spread infectious virus.

Sulfonamides and Potentiated Sulfonamides

Mark G. Papich

The sulfonamides are one of the oldest groups of antimicrobial compounds still in use today. Sulfanilamide, an amide of sulfanilic acid, was the first sulfonamide used clinically. It was derived from the azo dye Prontosil. Other sulfonamides also share the same structure and the "sulfonamide" structure is prevalent among other drug classes, including nonsteroidal antiinflammatory drugs (NSAIDs), anticonvulsants, and diuretics. Sulfonamide antimicrobials have been in clinical use for 50 years, but resistance is common when these drugs are used alone (without addition of trimethoprim or ormetoprim). Previous editions of this textbook should be consulted for a review of this extensive historical database. Clinical use of sulfonamides in dogs, cats, horses, and some exotic and zoo animals usually relies on the addition of trimethoprim (trimethoprim–sulfonamide) or ormetoprim (e.g., ormetoprim–sulfadimethoxine) to broaden the spectrum and increase antibacterial activity against bacteria that are resistant to either drug used alone. Technically, trimethoprim and ormetoprim are chemically called *diaminopyrimidines,* but they will be referred to by their respective names in this chapter. In companion animals, trimethoprim–sulfonamide combinations have all but replaced single or combination sulfonamide (triple-sulfas) treatment regimens. Sulfonamide administration is restricted in food animals, particularly dairy cattle, because of a concern for drug residues.

Pharmacology of Sulfonamides

All sulfonamides are derivatives of sulfanilamide (structurally similar to para-aminobenzoic acid), which was, in the 1940s, the first sulfonamide discovered to have antimicrobial activity. Note that in some countries and certain formularies outside the United States, different spellings have been used for sulfonamides (e.g., *sulphamethoxazole* for sulfamethoxazole; *sulphadiazine* for sulfadiazine; *sulphadimethoxine* for sulfadimethoxine, and so forth). This textbook uses the United States Adopted Names (USAN) and United States Pharmacopeia (USP) official names throughout.

Many structural derivatives of sulfanilamide with differing pharmacokinetic and antimicrobial spectrums have been used in veterinary medicine to treat microbial infections of the respiratory, urinary, gastrointestinal, and central nervous systems (Figure 32.1). Susceptible organisms include many bacteria, coccidia, chlamydia, and protozoal organisms, including *Toxoplasma* spp. Treatment of protozoa infections is discussed in more detail in Chapter 42 of this book.

Sulfonamides are white crystalline powders that are weak organic acids, with solubility in water that varies among the specific drugs (ranging from slightly soluble to practically insoluble), and have a wide range of pK_a values, as shown in Table 32.1. The pK_a values of these compounds and their ionization are important because – among other properties – the antibacterial activity, solubility, and protein binding have been associated with the pK_a value (Mengelers et al., 1997). Drugs with high pK_a are less soluble and exhibit lower protein binding; drugs with low pK_a tend to have higher protein binding. The sulfonamides all share a similar structure, which contains a $–SO_2$ group linked to a benzene ring, and a para NH_2- group on N-4. An attached pyrimidine ring may contain zero, one, or two methyl groups (sulfamethazine, sulfamerazine, and sulfadiazine, respectively), which may undergo hydroxylation during metabolism. The other major site of metabolism is acetylation of the para-NH_2, which can vary among species (for example, dogs do not acetylate, which is discussed in Section Metabolism). Acetylated forms of the drug tend to be less soluble.

The sulfonamides exhibit large variation in the extent to which they bind to plasma proteins. In general, the plasma protein binding is higher than other antimicrobials (>70% in many animals), and ranges from 90% (sulfadimethoxine in some species) to as low as 50% (sulfamethazine in some species). In horses, the protein binding of trimethoprim was 20–30% and for sulfadiazine was 18–30% (Winther et al., 2011). Because they

Figure 32.1 Sulfonamides and their structures.

Table 32.1 Physical chemistry properties of sulfonamides, trimethoprim, and ormetoprim

Drug	pK_a	Log P
Sulfanilamide	10.1	−0.072
Sulfadimidine	7.7	0.691
Sulfamerazine	7.0	0.812
Sulfadiazine	6.4, 6.5, 6.6	0.631
Sulfadimethoxine	6.3, 6.2	1.648
Sulfachlorpyridazine	6.1, 6.0	1.305
Sulfamethoxazole	5.7, 5.9, 6.0	1.396
Sulfisoxazole	5.0, 4.9	2.259
Sulfadoxine	6.1, 6.3	1.271
Sulfaquinoxaline	5.5	1.68
Trimethoprim	7.12, 7.6	0.91
Ormetoprim	na	1.23

The pK_a is the dissociation rate constant. For some drugs, more than one pK_a value is listed because of variation among sources. For pK_a values, all sulfonamides are weak acids; trimethoprim and ormetoprim are weak bases. Log P is the logarithm of the partition coefficient between an organic solvent (oil) and water. The higher the Log P, the more lipophilic is the drug. Some values are from Mengelers et al. (1997) and van Duijkeren et al. (1994a).

are weak acids, sulfonamides are more soluble in alkaline than in neutral or acidic pHs; water solubility is enhanced when the sulfonamides are formulated as sodium salts or when in solution in more alkaline environments. Some sulfonamide solutions have pHs between 9 and 10, prohibiting extravascular use. Because solubility is decreased in acidic pH, they may become particularly insoluble and crystallize in renal tubules when urine pH is low, especially when high doses are administered, or animals are dehydrated or acidemic. To minimize crystalluria, yet allow administration of high doses, they have been formulated in combination with other sulfonamides. Each sulfonamide in a mixture of sulfonamides exhibits its own solubility in solution (law of independent solubility); that is, sulfonamides do not significantly affect the solubility of each other, but the antimicrobial effect is additive; thus the use of “triple-sulfas” (three sulfonamides formulated in solution together) allows increased efficacy without a significant increased risk of adverse effects (Bevill, 1988).

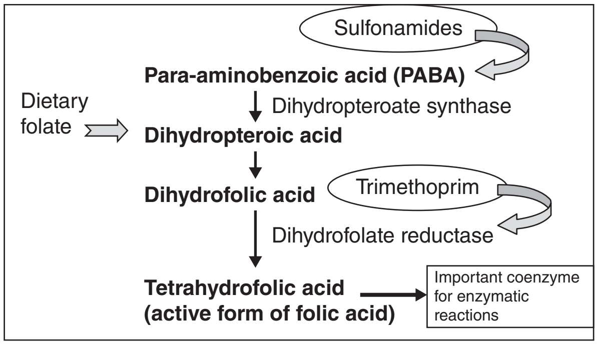

Figure 32.2 Simplified pathway for the action of trimethoprim–sulfonamide combinations. Sulfonamides provide a false substrate for para-aminobenzoic acid (PABA) inhibiting the synthesis to dihydropteroic acid, a precursor for synthesis to dihydro- and tetrahydrofolic acid. Trimethoprim inhibits the enzyme dihydrofolate reductase, an enzyme critical to the synthesis of tetrahydrofolic acid.

Mechanism of Action

Sulfonamides rely on the requirement of susceptible organisms to synthesize folic acid as a precursor of other important molecular molecules in the cell. Sulfonamides act as false substrates in the synthesis of folic acid. Trimethoprim and ormetoprim (diaminopyrimidines, discussed in Section Potentiated Sulfonamides) produce a synergistic effect when used together by inhibiting the enzyme dihydrofolate reductase.

Folic acid metabolism is presented in Figure 32.2. Para-aminobenzoic acid (PABA), pteridines, glutamic acid, and the enzyme dihydropterate synthase interact to form dihydropteroic acid, the immediate precursor to dihydrofolic acid. Dihydropteroic acid is enzymatically converted to dihydrofolic acid by dihydrofolate synthase, followed by another enzymatic conversion of dihydrofolic acid to tetrahydrofolic acid (THFA) via dihydrofolate reductase (DHFR). The combination of sulfonamides and trimethoprim inhibits formation of tetrahydrofolic acid at two steps. This action is synergistic and increases activity against organisms that could otherwise be resistant. Tetrahydrofolate is a coenzyme in a number of complex enzymatic reactions and also is a coenzyme in the synthesis of thymidylic acid (a nucleotide), which is a building block of DNA. Trimethoprim and sulfonamides are bacteriostatic by themselves; together, they can be bactericidal. Bacteria are more susceptible to this combination than to either drug when tested alone (White et al., 1981).

Trimethoprim–sulfonamides are formulated in a ratio of 1:5 (trimethoprim:sulfonamide). In the animal, it is usually cited that the optimum ratio to produce antibacterial activity is 1:20 (Bushby, 1980; van Duijkeren et al., 1994b). Testing for susceptibility using approved CLSI methods (CLSI, 2015) uses a ratio of 1:20 trimethoprim:sulfonamide. However, this ratio is often much lower in animals because the trimethoprim component is excreted faster than the sulfonamide and the optimum ratio may actually be much wider than the value of 1:20 cited in human medical references, and may be as low as 1:40.

Sulfonamide action is dependent on the chemical similarity with PABA. Therefore, sulfonamides act as a false substrate in this reaction and synthesis of THFA is inhibited. The sulfonamides are relatively safe to mammalian cells because mammals utilize dietary folate for the synthesis of dihydrofolic acid, and they do not require PABA. The enzyme dihydrofolate reductase of bacteria has a much higher affinity (50,000 to 60,000-fold, and in some references as high as 100,000-fold) for trimethoprim than mammalian dihydrofolate reductase.

The mechanism of action of sulfonamides on bacteria does not entirely explain the activity against protozoa. Sulfonamides may inhibit protozoal dihydrofolate synthetase. Protozoal dihydrofolate reductase also is susceptible to the action of trimethoprim, which may explain some of the effect to support the use of these drugs for protozoal infections (treatment of protozoa infections is discussed in Chapter 42).

Clinical Uses and Microbial Susceptibility

The spectrum of activity for the sulfonamides is broad, affecting gram-positive, gram-negative, and many protozoal organisms. Sulfonamides have been used clinically for approximately 50 years and many organisms once susceptible to the sulfonamides are now resistant. To increase the activity, most of the sulfonamides used in clinical practice are combinations with either trimethoprim or ormetoprim (diaminopyrimidines). These combinations (referred to in this chapter as *trimethoprim–sulfonamides,* but also referred to in clinical practice as *trimethoprim–sulfa* or simply abbreviated as *TMP/SU*) have increased the activity.

Administration of a single sulfonamide, or combination of sulfonamides, continues to be used in some livestock practices. In the United States, there are no approved formulations of trimethoprim–sulfonamides available for food animals, but trimethoprim–sulfadoxine is available in some countries.

The susceptibility/resistance patterns of sulfonamides and the trimethoprim–sulfamethoxazole combination against the most commonly encountered veterinary pathogens has been reported (van Duijkeren et al., 1994a, 1995; Bade et al., 2009; Winther et al., 2011). The activity of these agents has allowed for treatment of common respiratory infections, urinary tract and soft tissue infections, and intestinal infections (intestinal protozoa). Susceptible organisms include *Arcanobacterium*, *Bacillus* spp., *E. rhusiopathiae, L. monocytogenes, Streptococcus* spp., (*Streptococcus equi* subsp. *zooepidemicus* from horses), and protozoa (coccidia and *Pneumocystis carinii*).

The wild-type strains of following organisms are usually susceptible to the trimethoprim–sulfonamide (or ormetoprim–sulfonamide) combination: *Pasteurella* spp., *Proteus* spp., *Salmonella* spp., *Histophilus* (formerly *Hemophilus*), the protozoa *Toxoplasma,* and coccidia. Other bacteria that may be susceptible, but for which resistance can develop, include *Staphylococcus* spp., *Corynebacterium, Nocardia asteroides, Stenotrophomonas maltophilia,* and bacteria of the Enterobacteriaceae (*Klebsiella, Proteus, Enterobacter,* and *Escherichia coli*).

The organisms that are consistently resistant to trimethoprim–sulfonamide combinations include: *Pseudomonas* spp., *Chlamydia spp.,* and *Bacteriodes*. One should cautiously interpret trimethoprim–sulfonamide susceptibility for *Enterococcus spp*. Although *Enterococcus* may appear susceptible to trimethoprim–sulfonamides using in vitro tests, it escapes the antifolate activity of the drug in vivo by its unique ability to incorporate preformed exogenous folates (Wisell et al., 2008). Sulfonamides alone are not active against *Enterococcus* spp. Clinical failures are reported despite in vitro susceptibility and microbiology laboratories should not report the susceptibilities of *Enterococcus* to trimethoprim–sulfonamides.

The activity of trimethoprim–sulfonamides against anaerobic bacteria can be variable. When measured in vitro, trimethoprim–sulfonamides have good activity against anaerobic bacteria (Indiveri and Hirsh, 1986), but clinical results are not as good (Dow, 1988) because thymidine and PABA (inhibitors of trimethoprim–sulfonamide activity) may be present in anaerobic infections.

Trimethoprim–sulfonamides have been used to treat infections caused by protozoa (including *Toxoplasma gondii*) and intestinal coccidia. Trimethoprim–sulfonamide combinations have also been used to treat equine protozoal myeloencephalitis (EPM) caused by *Sarcocystis neurona.* (Use of pyrimethamine for treating EPM and treatment of protozoa infections is discussed in Chapter 42.)

Interactions Affecting Antimicrobial Activity

Components found in some tissue environments may inhibit trimethoprim–sulfonamide activity. For example, thymidine and PABA present in infected tissue – may interfere with activity. This has been demonstrated in tissue cages in horses. Ensink et al. (2005) showed an inability to eliminate the infection in an infected environment, despite in vitro sensitivity. They cited inhibitors – such as PABA and thymidine – present in abscessed and infected tissues that may inhibit the effects of these drugs. In another study in which trimethoprim–sulfadoxine was administered to cattle with infected tissue cages (Greko et al., 2002), it was shown that high levels of thymidine in the tissue cage fluid inhibited trimethoprim and compromised the ability to eradicate the infection.

Susceptibility Testing

For susceptibility testing, trimethoprim–sulfamethoxazole (1:20 ratio of trimethoprim:sulfamethoxazole) should be used, even when trimethoprim–sulfadiazine is used for therapy (CLSI, 2013, 2015). There are no quality control (QC) ranges developed for trimethoprim–sulfadiazine, and tests using trimethoprim–sulfamethoxazole are expected to give equivalent results. Winther et al. (2011) showed that there were no significant differences observed between the minimal inhibitory concentration (MIC) of sulfadiazine and sulfamethoxazole for individual bacterial strains, confirming that sulfamethoxazole is an effective surrogate for susceptibility testing of sulfadiazine. The CLSI susceptibility testing standards state that Mueller–Hinton agar containing excessive amounts of thymidine or thymine can reverse the inhibitory effect of sulfonamides and of trimethoprim, which may result in false-resistant reports (CLSI, 2013). Susceptibility testing agar that is as thymidine free as possible should be used. The current CLSI interpretive categories (CLSI, 2015) do not provide veterinary-specific interpretations; therefore, the human breakpoint is used by laboratories to predict susceptibility. For *Staphylococcus* spp. and the Enterobacteriaceae the susceptible breakpoint is ≤2/38 (trimethoprim/sulfonamide) and for *Streptococcus* spp. the breakpoint is ≤0.5/9.5 (trimethoprim/sulfonamide).

Drug Resistance

Resistance by many bacterial and protozoal organisms has become widespread due to the extensive use of sulfonamides over many years (Huovinen, 2001). Resistance occurs via efflux pumps, failure to penetrate the organism, and changes in target enzymes. Resistance can be transferable. Chromosomal resistance tends to occur slowly and confers resistance via impaired drug penetration into the microbial cell, producing an insensitive dihydropteroate enzyme and an increased production of PABA. Plasmid-mediated resistance, the most commonly encountered form of sulfonamide resistance, occurs quickly and manifests itself via the impaired drug penetration mechanism in addition to producing sulfonamide-resistant dihydropteroate synthase enzymes. If an organism becomes resistant to one sulfonamide, it is generally resistant to all other sulfonamides. Resistance to trimethoprim occurs via overproduction of the dihydrofolate reductase enzyme or synthesis of an enzyme that resists binding of the drug.

Pharmacokinetics of Sulfonamides

Pharmacokinetics of sulfonamides, trimethoprim, and related drugs used in veterinary medicine are listed in Tables 32.2, 32.3, 32.4, 32.5, and 32.6.

Oral Absorption

In dogs, absorption is excellent and not affected by feeding (Sigel et al., 1981). There has been considerable interest in the oral absorption of trimethoprim–sulfonamide combinations in horses and the effect of feeding. When trimethoprim-sulfonamides are administered to a horse that has not been fed, rapid absorption occurs, but is not as complete as for dogs or people. Nevertheless, oral administration is sufficient in horses to produce effective results. The fraction absorbed for trimethoprim was reported to be 67%, and for sulfadiazine 58%, but for both components the variability was high (van Duijkeren et al., 1994c). Oral absorption in another study in horses was 90.2% for intragastric administration and 74.45% for the oral paste (Winther et al., 2011). For trimethoprim in the same study it was 71.5% oral absorption for the intragastric administration and 46% for the oral paste (Winther et al., 2011). In that study the absorption of trimethoprim–sulfadiazine was likely diminished by feeding. When trimethoprim–sulfadiazine was administered to horses as an oral suspension and compared to the equine paste, the absorption from the suspension was higher for both drugs compared to the paste, that is 136% and 118% of the paste AUC concentrations for sulfadiazine and trimethoprim, respectively (McClure et al., 2015). In another study (van Duijkeren et al., 1994c) the oral paste was compared to two compounded formulations (mixed with syrup and water or carboxymethylcellulose gel). In this comparison, all three formulations were judged to be equivalent. When administered to horses that have been fed or when it is added to the horses' feed concentrate, a delayed and biphasic absorption is observed (van Duijkeren et al., 2002, 1995). When trimethoprim sulfachlorpyridazine was administered to horses, oral absorption was delayed, with the first peak appearing 1 hour after dosing and the second appearing 8–10 hours postdosing. Dual absorption peaks were not found after nasogastric administration (van Duijkernen et al., 1995). The best explanation for this phenomenon is that that there is an initial peak of absorption in the small intestine where much of drug absorption is known to occur. However, the drug that is bound to feed (adsorption) is unavailable for absorption until it travels to the cecum and, after digestion of the carbohydrates, the drug is released, producing a delayed and biphasic peak in absorption. Trimethoprim–sulfachlorpyridazine can bind to equine cecal contents 60–90%, which supports the theory of the "double peak". Feeding also decreased the systemic availability from 70% when fasted to 45% when fed (van Duijkernen et al., 1996).

In ruminants, age and diet can markedly affect trimethoprim and oral sulfadiazine disposition in calves (Guard et al., 1986; Shoaf et al., 1987). Orally administered sulfadiazine (30 mg/kg) was absorbed very slowly in those calves fed milk diets, with absorption slightly higher in ruminating calves. Trimethoprim was absorbed in preruminant calves, but not absorbed in mature ruminants after oral administration (Shoaf et al., 1987), probably because of inactivation in the rumen.

Sulfasalazine is not used for the antibacterial properties, but is used to treat inflammatory disease of the large intestine in small animals (discussed in more detail in Chapter 46). It is not absorbed as a whole molecule but rather is cleaved into two more active compounds by native resident colonic bacteria.

Distribution

Sulfonamides distribute to most body fluids, but are not distributed to tissues as extensively as trimethoprim. Generally, sulfonamide tissue concentrations are lower than plasma concentrations (approximately 20–30% of corresponding tissue concentration), but distribution to extracellular fluids is generally high enough to produce effective concentrations against susceptible pathogens. High protein binding affects the distribution and markedly increases the half-life of sulfonamides.

Sulfonamides are weak acids and trimethoprim is a weak base (Table 32.1). The ionization affects distribution, which favors the distribution and ion trapping of trimethoprim in tissues (intracellular environment is typically more negative than plasma). Therefore trimethoprim has a higher volume of distribution than sulfonamides. Also, because sulfonamides are weak acids, the pH-partition hypothesis shows that these drugs do not attain therapeutic concentrations in milk; however, enough passive diffusion occurs to limit their use in dairy cattle.

The prostate is another example in which pH-dependent distribution is known to occur (Robb et al., 1971). Sulfadiazine being a weak acid, penetrated the prostate to approximately 11% that of the mean plasma concentration. Because trimethoprim is a weak base (pK_a of 7.3) the concentrations in the prostate are higher owing to ion trapping. The concentration in the prostatic

fluid has been measured to be 380% higher than that of plasma. Consequently, trimethoprim–sulfonamide combinations are an acceptable choice for treating infections of the prostate.

In horses, studies have been conducted to examine tissue concentrations in urine, peritoneal fluid, endometrium, and synovial fluid (Brown et al., 1983, 1988, 1989) of trimethoprim or ormetoprim–sulfonamide combinations. In each tissue, drug concentrations were adequate for treating infections in these sites. Urine concentrations – as expected because of the route of elimination – were much higher than plasma, but, otherwise, the plasma concentration and tissue concentration curves were parallel. The only tissue in

[b] One mare studied.

which drug concentrations are low is the central nervous system (Brown et al., 1988). Although trimethoprim–sulfonamides can be used to treat CNS infections, higher doses may be required in order to reach effective concentrations (Brown et al., 1988). Administration of dimethylsulfoxide (DMSO) concurrently does not increase the penetration across the blood–brain barrier (Green et al., 1990).

Metabolism

Metabolism and elimination have been examined in several of the veterinary species. One phenomenon that is apparent from these studies is that herbivores metabolize sulfonamides and trimethoprim at a faster rate and more extensively than carnivores or omnivores. This may be caused by a higher metabolic capacity among herbivores – because of the nature of their diet and compounds to which they are exposed – compared to carnivores. Metabolic pathways are discussed in more detail by Nouws et al. (1988c, 1987). Acetylation of the NH_2 group on N-4 is a major mechanism of metabolism. Hydroxylation of the methyl group on the pyrimidine ring, in addition to carboxylation, also occurs. The extent to which these metabolites are produced is drug- and species-dependent. Acetylation and hydroxylation increases the polarity of the sulfonamides, which increases excretion (Nouws et al., 1988c). Acetylation (mainly occurring in the liver and lung) is the major pathway by which sulfonamides are metabolized in most species. Acetylated metabolites are the major urinary metabolites in cattle, sheep, and swine. The canine (dogs and other canine species) lacks the ability to acetylate aromatic amines, relying on alternative metabolic pathways to convert sulfonamides to less active forms. Acetylated metabolites are less soluble than the parent compounds and increase the risks of renal tubular injury caused by precipitation and crystal formation. Glucuronide conjugation and aromatic hydroxylation are two additional metabolic pathways by which sulfonamides are metabolized in animals. Glucuronide metabolites are water soluble and are excreted in urine, decreasing the risk of precipitation in renal tubules. Deacetylation, oxidation, deamination, conjugation with sulfate, and cleavage of heterocyclic rings of sulfonamide molecules have also been reported (Bevill, 1988). Regardless of the metabolic pathway taken, metabolites have either reduced therapeutic activity (hydroxy metabolite) or are therapeutically inactive (N4-acetyl metabolite).

Excretion

Sulfonamides that are capable of obtaining therapeutic blood concentrations are excreted by the kidneys, either as the parent compound or as metabolites via glomerular filtration (unbound to plasma proteins). Subsequently, urine concentrations are consistently higher than the corresponding plasma drug concentrations (approximately 10 times higher for trimethoprim and 30 times higher for the sulfonamides), which aids in the treatment of lower urinary tract infections. There also is some active carrier-mediated proximal tubular excretion and passive absorption of the nonionized drug from the distal tubular fluid. Small concentrations of sulfonamides are also excreted in the tears, feces, bile, milk, and sweat. Low urine pHs favor tubular reabsorption and hence longer half-lives of the sulfonamides, whereas alkalinization of the urine increases urinary excretion by slowing this pH-dependent passive reabsorption in the tubules. Tubular reabsorption is responsible for the long half-lives observed for some sulfonamides. Nonabsorbed sulfonamides intended for intestinal activity are primarily eliminated via the feces, with little of the active or metabolized drug being absorbed systemically to be excreted by these renal mechanisms.

Adverse Effects Caused by Sulfonamides

Sulfonamides can produce a variety of adverse effects in animals. Likewise, when trimethoprim- or ormetoprim–sulfonamide combinations are administered, the adverse effects are primarily attributed to the sulfonamide component.

Crystalluria

Crystalluria, hematuria, and renal tubule blockage can occur owing to precipitation of the sulfonamide in the glomerular filtrate of the kidney. Subsequently, crystals of sulfonamides can form in the renal tubules. This problem is not as important as it once was because it was caused primarily from older insoluble preparations. Sulfadiazine is the least soluble and can precipitate in renal tubules at acidic pH. Even though this complication is rare with the current use of sulfonamides, one should ensure that patients are well hydrated when receiving sulfonamides because renal failure caused by sulfonamide crystals has been reported in human patients that are dehydrated. The tubular blockage has been anecdotally reported in animals, but with current formulations it is not considered an important clinical problem. It is noteworthy that this problem is more likely with acetylated metabolites of sulfonamides, which are not formed in dogs.

Keratoconjunctivitis Sicca

Keratoconjunctivitis sicca (KCS), also known as “dry eye”, is a lack of adequate tear production resulting in ocular inflammation, irritation, and susceptibility to infection. Several cases of sulfonamide-induced KCS have been reported in dogs treated with sulfasalazine, sulfadiazine, and sulfamethoxazole (Morgan and Bachrach, 1982; Slatter and Blogg, 1978; Collins et al., 1986). The reaction is seen most commonly after chronic treatment, but cases have been reported that received only short-term administration. Berger et al. (1995) observed 33 dogs of various breeds for the occurrence of KCS after trimethoprim–sulfadiazine treatment, as characterized by changes in the Schirmer tear test values. There has been disagreement as to whether this effect is caused by an intrinsic dose-related effect, or is idiosyncratic. The prognosis appears to depend on the animal’s age and duration of exposure (Morgan and Bachrach, 1982). Dogs treated with sulfonamides should have tear production checked periodically.

The reaction apparently is caused by a lacrimotoxic effect of the sulfonamide component (toxic to the lacrimal acinar cells). The lacrimotoxic effect may be caused by the nitrogen-containing pyridine ring on the lacrimal acinar cells (Collins et al., 1986; Slatter and Blogg, 1978). Reversal of KCS may or may not occur once sulfonamide therapy has been discontinued.

Hypersensitivity

A delayed hypersensitivity reaction has been described primarily in dogs (Trepanier, 1999; Trepanier et al., 2003). The reaction may be caused by either sulfadiazine, sulfadimethoxine, or sulfamethoxazole. Doberman Pinschers may be more susceptible than other breeds (Giger et al., 1985; Cribb, 1989; Cribb and Spielberg, 1990). This may be a serum sickness reaction (type III hypersensitivity) or involve another mechanism of cytotoxicity and hypersensitivity, or may be idiosyncratic (Trepanier, 2004). The lesions include, but are not limited to, glomerulopathy, polymyositis, polyarthritis, skin rash, skin eruptions, fever, hepatotoxicity, thrombocytopenia, neutropenia, and anemia (Giger et al., 1985; Cribb, 1989; Rowland et al., 1992). The reaction is caused by the sulfonamide component rather than trimethoprim (Giger et al., 1985). In affected dogs, the clinical signs quickly resolved after the sulfonamide was discontinued. However, some problems such as hepatopathy did not resolve in dogs after the initial drug-induced injury (Trepanier et al., 2003). There is some evidence that a reaction to a metabolite of the sulfonamide, rather than an immunological reaction to the parent drug is responsible for these signs (see Section Effect of Acetylator Status on Adverse Reactions).

Hepatic Necrosis

A component of the hypersensitivity reaction is hepatic necrosis. Trimethoprim–sulfadiazine and trimethoprim–sulfamethoxazole combination therapy in dogs has resulted in hepatic necrosis (Twedt et al., 1997; Dodds, 1997). Hepatotoxicity may be caused by a hypersensitivity reaction or a result of an abnormal metabolic pathway, which allows the production or accumulation of hepatotoxic metabolites.

Blood Clotting Disorders

Hypoprothrombinemia has been reported in dogs (Neer and Savant, 1992; Patterson and Grenn, 1975), in coyote pups (Brown et al., 1982), and in Leghorn chickens (Daft et al., 1989) given sulfaquinoxaline. Sulfaquinoxaline is unique among the sulfonamides in that it can induce hypoprothrombinemia in animals within 24 hours after dosing by lengthening prothrombin times. It is thought that this adverse effect is unrelated to the individual sulfonamide or to the quinoxaline portion of the sulfaquinoxaline molecule but occurs when the two entities are combined into a single molecule. Sulfaquinoxaline is not an anticoagulant in vitro, nor does it destroy or otherwise inactivate prothrombin. Nevertheless, sulfaquinoxaline can be an inhibitor of vitamin K epoxide reductase, and this inhibition is the most likely reason for the hypothrombinemic reaction seen in the reported cases of sulfaquinoxaline toxicosis. Treatment is by vitamin K_1 administration for 4–7 days, and recovery is usually uneventful.

Blood Dyscrasias

Anemia and thrombocytopenia have been associated with administration of sulfonamides (Weiss and Adams, 1987; Weiss and Klausner, 1990; Stockner, 1993). Mammals derive their folic acid preformed, either in the diet or from bacteria that produce the vitamin in the intestinal tract. The anemia induced by trimethoprim–sulfonamide combinations may be caused by decreased serum folate reductions, presumably by inhibiting the folate production by intestinal bacteria or by blocking its reduction to tetra- and dihydrofolate, resulting in lowered serum folate concentrations in the animal's serum, which eventually induce an anemia. Folate deficiency anemia is rare but should be monitored with long-term use. Some veterinarians administer folic acid or folinic acid (vitamin B supplements) to patients receiving trimethoprim–sulfonamides. Whether this is routinely necessary, or whether this is effective, is controversial and unproven.

Thrombocytopenia has been reported in animals and in humans (Sullivan et al., 1992; Dodds, 1993). The thrombocytopenia in animals, as in humans, is probably associated with an immune-mediated or hypersensitivity reaction. The thrombocytopenia usually resolves after the drug is discontinued.

Thyroid Metabolism Disorders

Both sulfamethoxazole and sulfadiazine have been associated with hypothyroidism in dogs. The effect is probably caused by the ability of sulfonamides to inhibit thyroid peroxidase activity. Studies have demonstrated that administration of trimethoprim–sulfamethoxazole at a dose of 30 mg/kg, q 12 h for 6 weeks, or 15 mg/kg q 12 h for as short as 3 weeks decreased thyroxine (T_4) levels in dogs and decreased thyroid stimulating hormone (TSH) response (Frank et al., 2005; Hall et al., 1993; Williamson et al., 2002). The hypothyroidism is reversible, and can return to normal in as short as 1 week, or in most dogs by 3 weeks, after discontinuing the drug (Hall et al., 1993; Williamson et al., 2002). One study (Panciera and Post, 1992) produced conflicting evidence in which administration of trimethoprim–sulfadiazine at a dose of 15 mg/kg, q 12 h for 4 weeks had no effect on total T_4, free-T_4, or TSH tests. Sulfadimethoxine has also been implicated as being goitrogenic to swine fetuses in late gestation (Blackwell et al., 1989).

Skin Reactions

Sulfonamides are among the most common drugs implicated in skin eruptions in people, especially the drug-induced Stevens–Johnson syndrome and toxic epidermal necrolysis (Roujeau et al., 1995). In dogs, skin reactions (drug eruptions) also are possible (Medleau et al., 1990). The skin reactions in dogs are believed to be a manifestation of the hypersensitivity reaction described in Section Hypersensitivity (Trepanier, 1999).

Effect of Acetylator Status on Adverse Reactions

Adverse effects in people have been associated with acetylator status. In slow acetylators a greater proportion of the drug may be directed to conversion of a more toxic metabolite, sulfonamide–hydroxylamine or nitroso compounds, which are more toxic to cells. Ordinarily, these metabolites are detoxified by glutathione conjugation, but some patients may lack this ability. Dogs lack ability to acetylate drugs; therefore, they may be more susceptible to adverse effects than other animals. There is evidence that some dogs are more susceptible to the adverse effects of the hydroxylamine–sulfonamide metabolite than mixed-breed dogs because of decreased ability to handle the metabolite, which may explain the higher incidence of adverse effects reported in Dobermans (Cribb and Spielberg, 1990). (Other drugs that are acetylated in people include dapsone and isoniazid and these also may present a higher risk of toxicity in dogs.)

Diarrhea

Diarrhea has been associated with trimethoprim–sulfonamide therapy in horses. However, this effect may not be any more common from trimethoprim–sulfonamides than from other orally administered antimicrobials in horses. When healthy horses were administered doses of 25 to 100 mg of sulfadiazine in combination with 5 to 20 mg/kg of trimethoprim there was no evidence of increased *Clostridium perfringens*–associated colitis (White and Prior, 1982). In another study, Gustafsson et al. (1999) administered trimethoprim–sulfadiazine twice daily for 5 days to horses and measured the effect on intestinal flora. There was an initial decline in bacterial numbers, but these rebounded and the authors concluded that this treatment did not produce a disturbance of the intestinal bacterial flora.

Carcinogenesis

Sulfamethazine has been demonstrated to induce thyroid hyperplasia in rats (Astwood et al., 1943; MacKenzie and MacKenzie, 1943; Swarm et al., 1973) and induce specific types of thyroid cancer in both mice and rats. Fullerton et al. (1987) found that male and female Fischer 344 rats fed diets containing 1200 or 2400 ppm of sulfamethazine had thyroid weights that were increased significantly more than controls and that these increased weights were most likely due to thyroid hyperplasia related to increased thyroid-stimulating hormone levels. Littlefield et al. (1989) fed sulfamethazine to mice and induced follicular cell adenomas of the thyroid gland after 24 months of continuous feeding at a 4800 ppm dose with focal follicular cell hyperplasia and other organ aberrations being noted at some of the lower doses of sulfamethazine. In a similar study, there was a statistically significant increase in the incidence of thyroid follicular cell adenocarcinomas in rats sacrificed after 24 months of continuous feeding of sulfamethazine, with other nonneoplastic lesions of the thyroid also being reported in other treatment groups. There are no reports that have associated sulfonamide administration with cancer in domestic animals.

Potassium Regulation

Trimethoprim has been associated with hyperkalemia in people and laboratory animals, but except for anecdotal accounts, this has not been well documented in veterinary species. The mechanism of hyperkalemia appears to be caused by inhibition of renal Na-K-ATPase in the face of intact H-K-ATPase activity. The effects of trimethoprim can mimic amiloride, a potassium-sparing diuretic. These effects could be potentiated by coadministration of angiotensin converting enzyme inhibitors (ACE inhibitors), such as enalapril or benazepril, or administration of an angiotensin receptor blocker.

Sulfonamides in Veterinary Medicine

Sulfadimethoxine

Sulfadimethoxine (Figure 32.1) is a long-acting sulfonamide that has been used alone or in combination with ormetoprim (ormetoprim–sulfadimethoxine) for the treatment of susceptible microbial infections of cattle, swine, horses, poultry, fish, and dogs, in addition to other vertebrate and invertebrate animals. The combination is discussed in Section Sulfadimethoxine–Ormetoprim.

Sulfadimethoxine pharmacokinetics have been reported for many species. In dogs, the oral absorption is 49%, with a half-life of 13.1 hours (Baggot et al., 1976). Peak serum concentrations in dogs, at a dose of 55 mg/kg oral, was 67 μg/ml (mean). Systemic clearance in dogs is via the kidneys.

Sulfadimethoxine pharmacokinetics in cattle has been described by many investigators. Bourne et al. (1981) administered adult cattle with 107 mg/kg either intravenously (IV) or orally. In the IV study, sulfadimethoxine plasma concentrations peaked at 0.5 hours after administration and slowly declined over time, with the parent compound, acetylsulfadimethoxine, and a “polar” metabolite being found in the urine for at least 48 hours after the IV dose. The volume of distribution (Vd) was 0.315 l/kg in those cattle. In the oral study, plasma concentrations of sulfadimethoxine started low at 0.5 hours and gradually peaked at 10 hours after dose and then began to drop, with detectable levels of parent compound and all metabolites being found in the urine for at least 84 hours after dosing. Bioavailability of sulfadimethoxine was calculated to be 59.1%. Boxenbaum et al. (1977) administered 55 mg/kg IV sulfadimethoxine (40% solution) or 55 mg/kg orally to cattle, followed by 27.5 mg/kg sulfadimethoxine administered orally at

24, 48, and 72 hours after the initial loading dose. After IV injection, the half-life of sulfadimethoxine was determined to be 12.5 hours, with a volume of distribution of 0.31 l/kg. This study also confirmed that adequate plasma concentrations (>50 μg/ml) were maintained throughout the oral-dosing study, and this method could be used when IV administration was not possible. By comparison, a study by Wilson et al. (1987) demonstrated that sulfadimethoxine (27.5 mg/kg) in combination with ormetoprim (5.5 mg/kg) administered IV to cattle had a shorter half-life, 7.91 hours, and volume of distribution of 0.185 l/kg. When given the same dose orally, bioavailability of sulfadimethoxine was 56.6%.

Studies by Righter et al. (1979) examined the pharmacokinetics of sulfadimethoxine in mature, growing, and suckling pigs. Mature pigs dosed with 20, 50, or 100 mg/kg of sulfadimethoxine IV had volume of distribution values of 0.178, 0.258, and 0.331 l/kg and total body clearance of 4.21, 5.54, and 7.37 ml/kg/h, respectively. The pharmacokinetic parameters of 55 mg/kg sulfadimethoxine given IV to growing and suckling pigs have also been reported. Suckling pigs (1–2 weeks old) had sulfadimethoxine half-lives of 16.16 hours, volume of distribution of 0.483 l/kg, and total body clearance of 20.9 ml/kg/h. In contrast, growing pigs (11–12 weeks old) had sulfadimethoxine half-lives of 9.35 hours, volume of distribution of 0.347 l/kg, and total body clearance of 26.1 ml/kg/h, indicating an age-related effect of sulfadimethoxine pharmacokinetics in young pigs. Weanling pigs consuming water dosed with 0.05 g sulfadimethoxine/100 ml showed mean plasma concentrations of 80 ppm 12 hours after introduction of the medicated water, with plasma concentrations declining to approximately 50 ppm thereafter. Total water consumption was not affected, which indicated that sulfadimethoxine may be of therapeutic use in swine provided that water consumption is maintained throughout the medication period. Mengelers et al. (1995) dosed 34–40 kg healthy and febrile (inoculated endobronchially with *Actinobacillus pleuropneumoniae* toxins) pigs with 25 mg/kg sulfadimethoxine and 5 mg/kg trimethoprim intravenously. Sulfadimethoxine plasma half-lives for both healthy and pneumonic pigs were not significantly different (approximately 13 hours). Trimethoprim half-lives were not significantly different between healthy and pneumonic pigs (approximately 2.7 hours); however, the half-lives were significantly shorter than the half-life of sulfadimethoxine. In addition, the volume of distribution values of healthy and pneumonic pigs receiving sulfadimethoxine were not significantly different (approximately 0.25 l/kg), but trimethoprim did show significant differences between healthy (1.21 l/kg) and pneumonic (1.49 l/kg) pigs. The mean area under the curve (AUC) of trimethoprim was decreased and the total body clearance was increased in the febrile pigs, but with no significant changes in these sulfadimethoxine pharmacokinetic parameters.

Sulfadimethoxine is available in a concentrated solution (e.g., Albon 12.5%) for cattle or poultry; oral suspension (e.g., 5% Albon Suspension), and tablets and boluses for dogs, cats, and cattle; extended release tablets (Albon SR); 40% injection used in dogs, cats, and cattle; and soluble powder that can be added to drinking water for cattle and poultry. The approved clinical use for this formulation is for treatment of intestinal coccidiosis, bacterial enteritis, fowl cholera, bacterial pneumonia, pododermatitis in cattle, skin and soft tissue infections in dogs and cats, and bacterial cystitis in dogs. On the product labels for treating bacterial infections, it states "for treatment of susceptible bacteria causing these infections." Because resistance can be common, some of the conditions listed above may not respond appropriately to treatment and may be outdated.

The clinical use of sulfadimethoxine has been described for turkeys (Epstein and Ashworth, 1989), dogs (Yagi et al., 1981; Fish et al., 1965; Dunbar and Foreyt, 1985; Imamura et al., 1986, 1989), primates (Adamson et al., 1970; Bridges et al., 1968), lobsters (James and Barron, 1988), channel catfish (Squibb et al., 1988), and rainbow trout (Kleinow and Lech, 1988). Detection of violative levels of sulfadimethoxine residues in channel catfish has also been reported (Walker and Barker, 1994).

Sulfamethazine (Sulfadimidine)

Sulfamethazine (sulfadimidine) (Figure 32.1), like many sulfonamides, has been utilized for decades in veterinary medicine; hence, the veterinary literature contains many reports on its usage in a wide variety of animals, including cattle, horses, swine, poultry, small ruminants, and rabbits (among others). Table 32.2 summarizes some of the pharmacokinetic parameters of sulfamethazine in animals.

Sulfamethazine has been administered to cattle and swine, and is formulated for use in drinking water (Church et al., 1979), as a feed additive, an extended-release bolus, and an IV preparation. Sulfamethazine has been marketed as a sole treatment and in combination with other antimicrobials, such as other sulfonamides, tylosin, chlortetracycline, and procaine penicillin G.

The product labels for sulfamethazine products include uses for treating intestinal coccidiosis, bacterial enteritis, pneumonia, and pododermatitis in cattle. Sulfamethazine is available as an oral solution for calves, poultry, pigs, and cattle. It is available as a 12.5% solution to be added to drinking water. It is also available as a powder to be added to the drinking water of these species. Tablets (Sulmet 2.5 and 5-gram tablets) are also available for large animals, as well as extended-release tablets (e.g., Sulfa-Max) in a range of sizes for calves and adult cattle. Triple-sulfa products containing sulfamethazine (sulfamethazine, sulfanilamide, and sulfathiazole) as well as sulfamethazine–sulfathiazole combination oral powder are no longer available in the United States, but may still be available in other countries.

The basic pharmacokinetic parameters of sulfamethazine in cattle have been reported by Bevill et al. (1977a) and Nouws et al. (1988c), among many others. Of particular interest are the oral forms of sulfamethazine that have been formulated in extended-release (sustained-release) form for cattle. Several reports on the efficacy and clinical uses of the extended-release form of sulfamethazine in cattle are available (Clark et al., 1966; Ellison et al., 1967; Miller et al., 1969; Carlson et al., 1976). This sustained-release formulation has been reported to achieve blood concentrations sufficient for susceptible bacteria within 6–12 hours after oral administration and to maintain or exceed that level for 2–5 days after dosing. The sustained-release formulation of sulfamethazine has been reported to be effective for treating bovine respiratory disease, diphtheria, and pneumonia in cattle (Carlson et al., 1976; Clark et al., 1966). Clearance of sulfamethazine and its metabolites in cattle are age and dose dependent (Nouws et al., 1986a, 1985b, 1983; Lapka et al., 1980). Several metabolites of sulfamethazine have been identified and described in both adult cattle and calves (Nouws et al., 1988c).

The pharmacokinetics of sulfamethazine and its metabolites are of particular interest in swine. Sulfamethazine and its metabolites were often associated with violative levels in pork products because of sulfamethazine's widespread use as a swine feed additive. Sulfamethazine has been used extensively to treat a host of susceptible microbial infections in swine, including *Salmonella typhisuis* (Fenwick and Olander, 1987) and *Bordetella bronchiseptica* (Kobland et al., 1984). Sulfonamides were one of the most common causes of food-residue violations reported by the US Food Safety Inspection Service, with swine being the food-animal species with the greatest number of residue violations (Sweeney et al., 1993).

Pharmacokinetic parameters for swine have been described by Sweeney et al. (1993) and others (see Table 32.2), including pharmacokinetics of metabolites (Nouws et al., 1989a, 1986b). Several studies have used radiolabeled (Mitchell et al., 1986; Mitchell and Paulson, 1986) and nonradiolabeled (Biehl et al., 1981; Ashworth et al., 1986) sulfamethazine to determine the elimination patterns of sulfamethazine and its metabolites from the tissues in swine. Other studies have shown that the major metabolites produced from sulfamethazine metabolism in swine are N_4-acetylsulfamethazine, N_4-glucose conjugate of sulfamethazine, and desaminosulfamethazine (Mitchell et al., 1986). Studies using pigs fed 110 ppm of ^{14}C-sulfamethazine in the feed for 3–7 days, euthanized, and their tissues examined for total radioactivity and metabolite content found the highest concentration of radioactivity in the gut (undigested feed). Blood, kidney, urine, and liver all had high concentrations of radioactivity (i.e., parent compound and metabolite). Adipose tissue contained the least amount of radioactivity of all tissues assayed (Mitchell et al., 1986). Specific metabolites found in these and other tissues of swine given ^{14}C-labeled sulfamethazine in the feed have been reported by Mitchell and Paulson (1986).

Other studies have also reported on sulfamethazine residues in swine (Ashworth et al., 1986; Biehl et al., 1981). In addition, sulfamethazine and its metabolites have been described in pigs using physiological based pharmacokinetic (PBPK) models (Buur et al., 2005, 2006; Mason et al., 2008). These studies demonstrated significant amount of variability in disposition and metabolism, which would suggest potential for tissue residue violations with minor differences in dosing, environmental contamination, or in the presence of disease.

Cattle and swine are the two major species in which sulfamethazine is approved for use, with fewer reports in other species. Pharmacokinetic parameters and/or tissue-depletion kinetics of sulfamethazine and metabolites have been established in ponies (Wilson et al., 1989; Nouws et al., 1987) and horses (Nouws et al., 1985a). Studies on pharmacokinetics of sulfamethazine in goats (Abdullah and Baggot, 1988; Witcamp et al., 1992; Nouws et al., 1988b, 1989b; Elsheikh et al., 1991; Youssef et al., 1981; van Gogh et al., 1984; Witcamp et al., 1993), sheep (Srivastava and Rampal, 1990; Bourne et al., 1977; Bevill et al., 1977c; Bulgin et al., 1991; Nawaz and Nawaz, 1983), dogs (Riffat et al., 1982), chickens (Righter et al., 1971; Nouws et al., 1988a; Goren et al., 1987), rabbits (Yuan and Fung, 1990), mice (Littlefield et al., 1989), buffalo (Singh et al., 1988), camels (Younan et al., 1989), and carp and rainbow trout (van Ginneken et al., 1991) also have been published.

Lashev et al. (1995) described altered pharmacokinetics in roosters treated with a single 50 mg/kg IV dose of sulfadimidine only or IV sulfadimidine after 2 weeks of four 3.5 mg/kg subcutaneous (SC) testosterone treatments. Normal and castrated roosters provided no significant differences in half-life values, which ranged from 7.62 hours (castrated) to 9.38 hours (intact). Roosters pretreated with testosterone and then dosed with sulfadimidine had half-lives of 23.85 hours, as well as significantly decreased clearance and volume of distribution. Chickens metabolize sulfamethazine in relatively equal parts through hydroxylation and acetylation. It was hypothesized in this study that the acetylation pathway of sulfamethazine metabolism was retarded by the testosterone treatments and resulted in the prolonged half-lives.

Sulfaquinoxaline

Sulfaquinoxaline (Figure 32.1) has been used primarily for control of coccidia and some susceptible bacterial diseases in poultry. The veterinary literature also contains a few reports of sulfaquinoxaline use in rabbits (Eppel and Thiessen, 1984; Joyner et al., 1983) and dogs (Brown et al., 1982; Patterson and Grenn, 1975), but clinical use in these species is rare today.

Sulfaquinoxaline is available as an oral solution in a range of concentrations (20–32%). These solutions are intended to be mixed with drinking water. In some countries (but not the US) there are combinations of pyrimethamine and sulfaquinoxaline solution for administration to drinking water.

For the use in poultry, sulfaquinoxaline has been administered to control coccidiosis. Mathis and McDougald (1984) described the therapeutic effectiveness of sulfaquinoxaline and sulfaquinoxaline–pyrimethamine against several coccidia species of *Eimeria*. It was determined from that study that both sulfaquinoxaline and sulfaquinoxaline–pyrimethamine were highly effective against *E. acervulina* but less effective against *E. tenella*. In addition, the potentiated mixture was determined to be more effective against *E. tenella* than sulfaquinoxaline alone, although neither mixture was found to be particularly effective against any cecal coccidia. Amprolium was efficacious against cecal–dwelling forms of coccidia; hence amprolium has been combined with sulfaquinoxaline or sulfaquinoxaline–pyrimethamine to enhance the spectrum of activity. Ineffectiveness of sulfaquinoxaline–pyrimethamine against *E. tenella* has also been documented in another study (Chapman, 1989), underlining the importance of correct coccidia species identification before instituting anticoccidial therapy with sulfaquinoxaline or any other sulfonamide.

Banerjee et al. (1974) reported on the blood concentrations after administration of sulfaquinoxaline, which were in the therapeutic range. In that same study, sulfaquinoxaline was found in high concentrations in the liver, kidney, and cecum, with the lowest concentrations found in the yolk sac and brain. A single oral dose of ^{35}S-labeled sulfaquinoxaline in 1-week-old chicks showed rapid uptake from the gastrointestinal tract and wide distribution throughout the body, including crossing of the blood–brain barrier. At 0.5 hours after dosing, autoradiography showed that all tissues (brain, lung, liver, kidney, fat, and muscle), except the lens of the eye had measurable concentrations of sulfaquinoxaline. Similar findings resulted from IV administration of ^{35}S-labeled sulfaquinoxaline, and it was also found that excretion of sulfaquinoxaline by the bile and secretion by the cecal mucosa, crop, and gizzard probably occur. Oral absorption was higher (3.5 times) in birds infected with *E. acervulina* and *E. tenella* compared to uninfected birds (Williams et al., 1995). A study by Li et al. (1995) found that in 7- to 8-week-old male and female broilers given a single 200 mg/kg oral dose of sulfaquinoxaline, peak concentration times in plasma and liver were similar (4 hours) but were longer in the heart, kidney, and muscle (6 hours). The half-life of sulfaquinoxaline was shortest in the muscle (4.5 hours), with significantly longer half-lives in the heart (10 hours), plasma (11 hours), liver (13 hours), and kidney (18 hours).

The safety and efficacy of sulfaquinoxaline alone or in combination with trimethoprim (trimethoprim:sulfaquinoxaline ratio is 1:3) have been reported in poultry (White and Williams, 1983; Piercy et al., 1984; Sainsbury, 1988). A total dose of 30 mg/kg/day PO satisfactorily controlled experimentally induced colisepticemia and pasteurellosis in addition to five species of coccidia (White and Williams, 1983). A wide margin of safety has been shown for the 1:3 combination of trimethoprim:sulfaquinoxaline in poultry, although decreased appetite and water consumption and lowered egg production, egg weight, and hatchability were noted when these antimicrobials were incorporated in the feed or water in higher than recommended concentrations (Piercy et al., 1984).

Toxicosis from sulfaquinoxaline use in animals is rare. Toxicity from sulfaquinoxaline has occurred in Leghorn chickens (Daft et al., 1989), where a mortality of 47% was reported in a commercial flock given a 0.05% concentration of sulfaquinoxaline in the feed. Lesions included mildly enlarged livers; swollen and pale livers; hemorrhages on the epicardium, kidney, oviduct, small intestine, and cecum; pale bone marrow; gangrenous dermatitis; and some lung involvement was present. Patterson and Grenn (1975) reported on 12 adult Miniature Poodles that received 3.16 g/l of sulfaquinoxaline in the drinking water as treatment for coccidiosis suffered similar lesions as described above in poultry, in addition to depressed body temperature, pale mucous membranes, microscopic hemorrhages of the jejunum and ileum, and prolonged prothrombin times. Although the exact mechanism has not been reported, sulfaquinoxaline possesses an ability to produce a marked hypothrombinemia (see Section Adverse Effects Caused by Sulfonamides), even in animals receiving balanced diets containing adequate amounts of vitamin K. These animals also responded to vitamin K treatment. It is thought that this adverse effect is not related to the individual sulfonamide or quinoxaline portion of the sulfaquinoxaline molecule but occurs only when the two entities are combined. A similar toxicosis has also been reported in coyote pups treated with sulfaquinoxaline (Brown et al., 1982).

Sulfamerazine

Sulfamerazine (Figure 32.1) has primarily been utilized in adult sheep and lambs to treat susceptible microbial infections. In these ruminants, sulfamerazine has been used alone or in combination with other antibiotics (tylosin) and other sulfonamides (sulfamethazine, sulfadiazine).

The pharmacokinetics of sulfamerazine has been described for ewes and lambs. Hayashi et al. (1979) described the pharmacokinetics of sulfamerazine in ewes after either IV or oral administration of 107 mg/kg. After oral administration, systemic availability was 81 ± 19%. Urinary concentrations of parent compound and metabolites were also reported for both IV and PO dosing studies. Both routes produced appreciable concentrations of sulfamerazine and three metabolites in the urine (described as a polar metabolite acetylsulfamerazine). Intravenous sulfamerazine produced more parent compound and fewer metabolites were found in the urine, which is attributed to lack of rumen metabolism, while more metabolite than parent compound was found in the PO study because of conversion by rumen metabolism.

The pharmacokinetics of sulfamerazine has also been reported in neonatal and young lambs (Debacker et al., 1982). Lambs from birth to 16 weeks of age were administered either IV or PO, 100 mg/kg of sulfamerazine. In the IV study, it was found that the sulfamerazine half-life was longest in the first week of life (9–14 hours) and decreased to 4–7 hours by 9–16 weeks of age. The volume of distribution was highest during the first week of life and steadily decreased with age, while clearance of sulfamerazine was lowest in the first week of life (20–40 ml/kg/h) and steadily increased with age up to 9–16 weeks of age (50–80 ml/kg/h).

Sulfathiazole

Sulfathiazole use in veterinary medicine has declined. It has been formulated in combination with chlortetracycline HCl and procaine penicillin G, but reports of its use are rare and earlier editions of this text should be consulted for more details.

Sulfathiazole pharmacokinetics in sheep has been outlined by Koritz et al. (1977), and sulfathiazole tissue residues in sheep have been described by Bevill et al. (1977b). When 36 or 72 mg/kg of 5% aqueous solution of sulfathiazole sodium IV was given to ewe lambs, it cleared quickly from the plasma, with a low volume of distribution of 0.34 and 0.59 l/kg and half-lives of 1.2 and 1.4 hours, respectively. Ewes given 214 mg/kg orally of a 12.5% aqueous solution of sulfathiazole sodium had systemic bioavailability of approximately 73%, with a half-life of approximately 18 hours. Both oral and IV routes produce acetylsulfathiazole, and a third “polar” metabolite in the urine of these sheep. Sulfathiazole residues in sheep are highest in the kidney (308 ppm), followed by the liver (40 ppm), heart (34 ppm), shoulder muscle (23 ppm), leg and loin muscle (22 ppm), body fat (11 ppm), and omental fat (6.7 ppm). Residues quickly dropped to very low (<0.13 ppm) or to nondetectable levels by 24 hours after dosing in all tissues tested.

Pharmacokinetic parameters have also been reported for swine. Pigs given 72 mg/kg of sulfathiazole sodium IV had quick plasma elimination of the drug, with mean Vd of 0.54 l/kg and a biological half-life of 1.39 hours, similar to those for sheep. After a dose of 214 mg/kg orally, sulfathiazole had a Vd of 0.32 l/kg and a systemic bioavailability of 73%, identical to that of sheep.

Sulfasalazine (Salicylazosulfapyridine)

Sulfasalazine (Figure 32.3) was originally developed as a possible treatment for rheumatoid arthritis in humans. It was found, however, to be more effective in the treatment of inflammatory bowel disease. The most frequent use is to treat various forms of colitis (Aronson and Kirk, 1983). The gastrointestinal use is discussed in more detail in Chapter 46 of this book. Inflammatory bowel diseases (most commonly ulcerative colitis and Crohn’s disease) have been treated with sulfasalazine in humans.

Sulfasalazine consists of two components, 5-aminosalicylic acid and sulfapyridine, which are linked by an azo bond. This bond is broken by the bacterial enzymes in the colon (Figure 32.3). After oral administration, the sulfonamide component is absorbed systemically, but the 5-aminosalicylic acid component produces a local inflammatory effect in the colon. 5-aminosalicylic acid is also known as *mesalamine* and there are now other forms of mesalamine (e.g., olsalazine) or enteric-coated (pH-sensitive) tablets that release mesalamine in the colon, while avoiding the systemic effects of the sulfonamide component.

The intestinal antiinflammatory effects may be due to prostaglandin inhibition (Hoult and Moore, 1978), inhibition of leukotrienes, decreased intestinal oxygen free radicals (Del Soldato et al., 1985), or sulfhydryls (Garg et al., 1991).

Sulfadiazine

The most commonly used formulation containing sulfadiazine is a trimethoprim–sulfadiazine combination (e.g., Tribrissen and others). This combination will be discussed in more detail in Section Trimethoprim–Sulfadiazine, because of its common use. Sulfadiazine

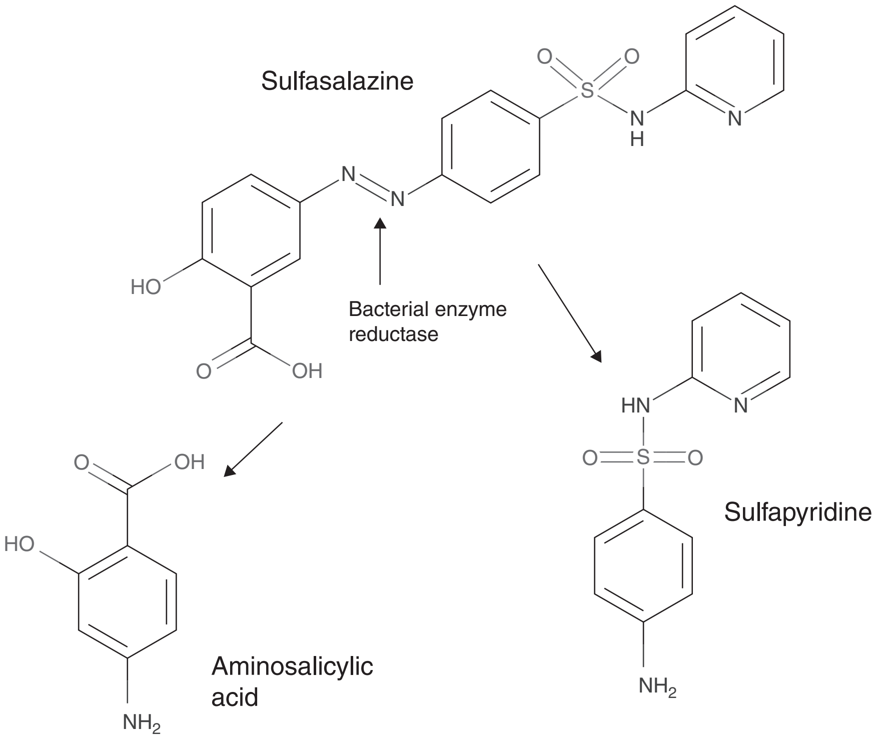

Figure 32.3 Structure of sulfasalazine, showing the reduction by bacterial enzymes in the colon (breaking the azo bond) to form 5-aminosalicylic acid and sulfapyridine. Sulfapyridine can be absorbed systemically but has no significant therapeutic effects; aminosalicylic acid has local antiinflammatory effects in the bowel.

(Figure 32.1) use alone has been reported in some studies. The pharmacokinetics are listed in Table 32.3. Sulfadiazine has been used to control plaque and gingivitis in dogs (Howell et al., 1989) and has attained concentrations in the cerebrospinal fluid (when administered IV) above the reported MIC values for many of the Enterobacteriaceae family (Vergin et al., 1984). In pigs, sulfadiazine administration was reported from various studies (Soli et al., 1990; Guise et al., 1986).

Sulfabromomethazine

Sulfabromomethazine is the brominated derivative of sulfamethazine and is considered a long-acting sulfonamide that is now rarely used. Sulfabromomethazine has a lower solubility than sulfamethazine, and single oral doses of the drug have been used to treat calf diphtheria and pneumonia, metritis, foot rot, and septic mastitis in cattle, with a repeated dose 48 hours later sometimes required. Use of sulfabromomethazine during the last 3 months of pregnancy should be avoided (Bevill, 1988).

Sulfaethoxypyridazine

Sulfaethoxypyridazine also is rarely used today. It is rapidly absorbed after oral administration to swine, sheep, and cattle and is extensively bound to plasma proteins. The parent compound and the N4-acetylated metabolite and another unidentified glucuronide conjugate seem to be the major urinary excretion products (Bevill, 1988). Sulfaethoxypyridazine can induce cataracts at some doses when fed to dogs and rats over a period of 27 and 118 weeks, respectively (Ribelin et al., 1967).

Sulfisoxazole

Sulfisoxazole has limited use today but has been used in the treatment of urinary tract infections in the dog and cat caused by susceptible bacteria (Bevill, 1988). The pharmacokinetics of sulfisoxazole has been studied in dogs, swine, and humans (Suber et al., 1981), as well as its delivery across the skin using iontophoresis (Inada et al., 1989). A formulation of combined trimethoprim–sulfisoxazole is available in some countries for injection of cattle.

Sulfachlorpyridazine

When used alone, sulfachlorpyridazine is administered most often to calves and pigs. Sulfachlorpyridazine powder, to be mixed into an oral solution (Vetisulid powder) or tablets (Vetisulid 2-gram tablets), has been administered to calves and pigs for treatment of enteritis at a dose of 33–49.5 mg/kg for calves and 44–77 mg/kg per day to pigs. There is also an injectable solution available (Vetisulid injection 200 mg/ml) for intravenous use in calves. Sulfachlorpyridazine has also been used in combination with trimethoprim and this combination is discussed in more detail in the section on potentiated sulfonamides.

Sulfachlorpyridazine is rapidly eliminated from the plasma following IV administration. Intramuscular injections in swine result in maximum blood concentrations within 30 minutes after injection, which are maintained for up to 3 hours (Bevill, 1988). A single 50 mg/kg IV dose of sulfachlorpyridazine demonstrated significantly different volume of distribution in cocks (0.34 l/kg) versus hens (0.36 l/kg), with the sulfonamide being more slowly excreted in hens (Lashev et al., 1995).

The pharmacokinetics of sulfachlorpyridazine after oral and intracardiac administrations has also been described in the channel catfish (*Ictalurus punctatus*), and the drug has been found to have a potential use in aquaculture (Alavi et al., 1993).

Other Sulfonamides

This chapter has discussed the major sulfonamides in use in veterinary medicine today, and briefly some minor sulfonamides even though their used has declined significantly. However, other sulfonamides exist that are not currently, or are no longer, used in the US markets. Other sulfonamides that may be of interest, either historically or because of use in other countries, include sulfadimethoxypyrimidine (Walker and Williams, 1972), sulfasomidine and sulfamethomidine (Bridges et al., 1969), sulfamethoxypyridazine (Garg and Uppal, 1997), sulfamethoxydiazine (Weijkamp et al., 1994), and sulfamethylphenazole (Austin and Kelly, 1966). The combination of sulfadimethoxine–sulfamethoxazole use in healthy and pneumonic pigs (Mengelers et al., 1995) has also been reported.

Previous editions of this textbook or the individual references listed here may be consulted for more in-depth information on the older and less commonly used sulfonamides not discussed in this chapter.

Potentiated Sulfonamides

The combination of sulfonamides with trimethoprim or ormetoprim (Figure 32.4) produces greater antibacterial activity than either drug used alone. Consequently, in humans, dogs, cats, horses, and occasionally other animals, these formulations are used more commonly than sulfonamides alone.

Sulfonamide and trimethoprim combinations have been reviewed in some depth by Bushby (1980) and van Miert (1994). An extensive review of trimethoprim–sulfonamide combinations in the horse is also available (van Duijkeren et al., 1994b). Although these reviews are several years old, the pharmacology and use in veterinary medicine has not changed substantially in 30 years.

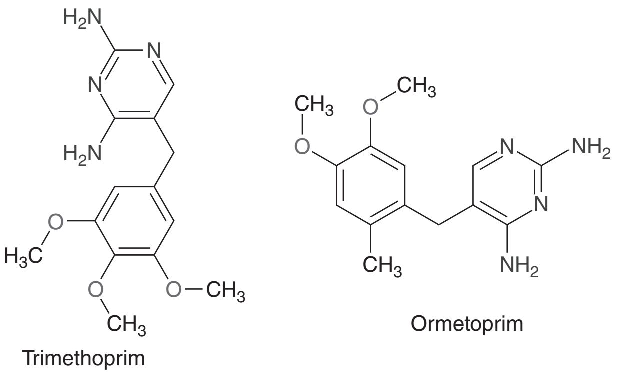

Figure 32.4 Structure of trimethoprim (left) and ormetoprim (right).

The pharmacokinetic parameters of diaminopyrimidines (trimethoprim, ormetoprim, and others) have been established for some species and are listed in Tables 32.5 and 32.6. Specific properties of these diaminopyrimidines are also discussed by Ascalone et al., 1986; Mengelers et al., 1990; Lohuis et al., 1992; Sutter et al., 1993; Wilson et al., 1987; Brown et al., 1989; Iversen et al., 1984; Vergin et al., 1984; Aschhoff, 1979.

The full range of combinations possible include a sulfonamide with trimethoprim (2,4-diamino-5-(3,4, 5-trimethoxybenzyl) pyrimidine), aditoprim (2,4-diamino-5-[4-(dimethylamino)-3,5-dimethoxybenzyl] pyrimidine), ormetoprim (2,4-diamino-5-[4,5-dimethoxy-2-methylbenzyl] pyrimidine), or tetroxoprim (2,4-diamino-5-[3,5-dimethoxy-4(2-methoxy ethoxy)benzyl] pyrimidine). These are commonly referred to as *potentiated sulfonamides.*

Trimethoprim–Sulfadiazine

Sulfadiazine is most often administered in combination with trimethoprim (e.g., Tribrissen and other veterinary products). This combination has been used for respiratory infections, urinary tract infections, urogenital infections, protozoal infections, bone and joint infections, and skin and soft-tissue infections. It is available as an oral paste (400 mg per gram, e.g., Tribrissen®) and oral suspension (Equilsul-SDZ®, 400 mg/ml). It also is available as a powder (e.g., Tucoprim®, Uniprim™) to be added to feed for horses. Feeding does not affect absorption of sulfadiazine in horses, but it may delay the absorption of the trimethoprim component. Tablets of sulfadiazine and trimethoprim (5:1 ratio) have been available in a range of sizes for small animals, but the availability of the small animal products has diminished in recent years. Injectable formulations have become less available, but

24% and 48% injections (e.g., Tribrissen®) have been used in a range of species.

Trimethoprim–sulfadiazine combination in a 1:5 ratio has been among the most popular antimicrobials in dogs, cats, and horses as a general "first-line" antimicrobial that can be useful for treating a wide variety of pathogens, in particular *Staphylococcus* spp., *Streptococcus* spp., and some gram-negative organisms, such as *Proteus mirabilis* spp., *Pasteurella* spp., and *Klebsiella* spp. However, resistance among the gram-negative bacilli *Enterobacteriaceae* can be common.

Dosing Recommendations

It is difficult to correlate plasma drug levels (and plasma elimination rates) with clinical efficacy and dosing intervals because trimethoprim is excreted faster (shorter half-life) than the sulfadiazine component; however, trimethoprim persists longer in some tissues than in the plasma and it is possible that tissue are maintained higher than plasma drug concentrations. Among the various species, doses range from 15 mg/kg twice daily, to 30 mg/kg twice daily. (See specific species recommendations.) Doses are generally listed as the combined product; that is, 30 mg/kg is equivalent to 5 mg/kg trimethoprim + 25 mg/kg of the sulfonamide.

The safety is generally acceptable for use in dogs, except for general concerns discussed for sulfonamides in this chapter. Specific toxicological studies have been conducted in both dogs and cats (Craig and White, 1976). In the Craig and White study, dogs were administered up to 300 mg/kg/day orally (10 times the recommended dose) of trimethoprim–sulfadiazine for as long as 20 days with no abnormal clinical signs or blood or serum chemistry abnormalities reported. Cats were more sensitive to adverse effects. When cats were administered 30 to 300 mg/kg/day orally for 10 to 30 days, the high dose (300 mg/kg) produced signs of lethargy, anorexia, anemia, leukopenia, and altered blood urea nitrogen (BUN).

Equine Use

Trimethoprim–sulfadiazine use in horses is common. Pharmacokinetics have been reported for horses (Tables 32.3 and 32.5) and dosing protocols have been established (McClure et al., 2015; White and Prior, 1982; Divers et al., 1981; Bertone et al., 1988). A common use in horses includes treatment of *Streptococcus equi* subsp. *zooepidemicus* and *Streptococcus equi* subsp. *equi* from horses (McCandlish and Thompson, 1979; McClure et al., 2015; van Duijkeren et al., 1994c). However, in tissue cages placed in horses, trimethoprim–sulfadiazine did not eliminate infection of *Streptococcus zooepidemicus* (Ensink et al., 2005). The inability to eliminate the infection in an infected environment may be caused by inhibitors – such as PABA and thymidine – present in abscessed and infected tissues that may inhibit the effects of these drugs.

For horses, the proper dosing regimen was reviewed by van Duijkeren et al. (1994c) and drug concentrations reported by Winther et al. (2011), and McClure et al. (2015). Drug concentrations of the oral paste are not as high as intragastric administration or the oral liquid suspension, but high enough for treatment. The conclusion reached from most studies in horses is that twice daily administration is needed because of the rapid elimination in horses – particularly of the trimethoprim component – and the need to maintain concentrations above the MIC throughout most of the dosing interval. This was confirmed in the studies by Winther et al. (2011) and McClure et al. (2015) for respiratory infections. In horses with joint infections the optimum dosage is 30 mg/kg q 12 h (Bertone et al., 1988). van Duijkeren et al. (2002) also concluded from an analysis of plasma concentrations that twice-daily administration to horses at 30 mg/kg (25 sulfadiazine; 5 trimethoprim) was necessary.

Small Animal Use

Trimethoprim–sulfadiazine combination was effective for treating urinary tract infections caused by *Staphylococcus intermedius* (now referred to as *S. pseudintermedius*) (Turnwald et al., 1986) as well as the more common pathogens such as *E. coli, Proteus mirabilis, Klebsiella pneumoniae,* and *Streptococcus* spp. (Ling and Ruby, 1979; Ling et al., 1984). Beagle dogs treated with trimethoprim–sulfadiazine (240 mg total of a 1:5 combination) once a day or the same daily dose divided into twice daily had high concentrations of both sulfadiazine and trimethoprim in their urine that greatly exceeded the MIC values for most susceptible pathogens (Sigel et al., 1981). The effectiveness for urinary tractions caused by *Enterococcus* spp. is doubtful based on the analysis by Wisell et al. (2008).

An overall success rate of 85% was reported in dogs and cats treated with a trimethoprim–sulfadiazine combination for microbial diseases involving the alimentary, respiratory, urogenital, skin, and other systems (Craig, 1972). A common use of trimethoprim–sulfadiazine is for the treatment of bacterial skin infections. Success rates of 90% (skin diseases either cured or improved) in bacterial skin infections; foot infections; interdigital abscesses; anal abscesses; and infections of the eye, ear, and mouth in dogs have been reported. A similar success rate was reported in cats (89%) with infections caused from bite wounds and other infections. Although good activity is expected against wild-type strains of *Staphylococcus pseudintermedius* isolated from dogs, methicillin-resistant strains are usually resistant.

Pharmacokinetic studies in dogs have reported that 30 mg/kg (25 sulfadiazine + 5 trimethoprim) administered once daily, should be adequate for most infections caused by susceptible organisms (Sigel et al., 1981). In a specific study in which response for treating skin infections was examined (Messinger and Beale, 1993), there was no difference in response between once- or twice-daily administration. However, the authors acknowledged that the sample size may have been too small to detect a significant difference. Supporting a once daily schedule, a study in dogs with skin infections showed that 30 mg/kg once daily is adequate (Pohlenz-Zertuche et al., 1992). These authors reported that 30 mg/kg of trimethoprim–sulfadiazine orally at 12- or 24-hour intervals were found to attain therapeutically useful concentrations of both trimethoprim and sulfadiazine in the skin (Pohlenz-Zertuche et al., 1992).

In dogs, it also has been used for *Bordetella bronchiseptica* (Powers et al., 1980), ocular infections (Sigel et al., 1981), and prostate infections. The distribution into the prostate is discussed in Section Distribution. The use for treatment of protozoan infections is discussed in more detail in Chapter 42 of this book.

Cattle Use

Trimethoprim–sulfadiazine has been used to treat infections in cattle (Slaughter, 1972), but because there are no longer any approved formulations of trimethoprim–sulfadiazine for cattle, the use has diminished. Nevertheless, the pharmacokinetics have been described in calves with values reported for tissue fluids (Shoaf et al., 1986). The pharmacokinetics of sulfadiazine and trimethoprim are reported for calves and in cattle in Tables 32.3 and Table 32.5. Calves given sulfadiazine subcutaneously (30 mg/kg) had a rapid absorption of the drug; age and diet had no effect on sulfadiazine or trimethoprim disposition in those calves (Shoaf et al., 1987). In another study by Guard et al. (1986), calves 1 day of age showed higher serum and synovial fluid concentrations of trimethoprim and sulfadiazine than did calves of 1 week or 6 weeks of age. Trimethoprim–sulfadiazine concentrations also have been documented in the cerebrospinal fluid of neonatal calves (Shoaf et al., 1989). Although rarely administered orally to cattle, as indicated in Section Oral Absorption, trimethoprim is absorbed in preruminant calves, but not absorbed in mature ruminants after oral administration (Shoaf et al., 1987).

Pig Use

Trimethoprim (8 mg/kg) –sulfadiazine (40 mg/kg) was administered orally to pigs to determine bioavailability and other pharmacokinetic parameters (Tables 32.3 and Table 32.5). Bioavailability of sulfadiazine was 89% and 85% in fasted and fed pigs, respectively, while the trimethoprim resulted in bioavailability values of 90% and 92%. After IV administration of trimethoprim (4 mg/kg) –sulfadiazine (20 mg/kg), sulfadiazine was detectable in plasma up to 30 hours after administration, while the trimethoprim was found in the plasma only during the first 12 hours after dosing (Nielsen and Gyrd-Hansen, 1994). Other species in which trimethoprim–sulfadiazine was investigated include carp (Nouws et al., 1993) and ewes (Youssef et al., 1981).

Trimethoprim–Sulfamethoxazole

The most common human formulation is trimethoprim–sulfamethoxazole (Bactrim and Septra) and it is sometimes referred to as *cotrimoxazole*. Although there are no registered veterinary formulations, the generic human formulation is inexpensive and has been used commonly in dogs and horses for oral administration.

Trimethoprim–sulfamethoxazole human formulations are available as liquid suspensions (48 mg/ml) or oral tablets (480 or 960 mg). The injectable formulation is 96 mg/ml (80 mg sulfamethoxazole + 16 mg trimethoprim). The injectable form should be given slowly IV. It has been used at a dose of 43.5 mg/kg (combined drugs) to treat CNS infections in foals.

Because of the availability of the human generic formulation of trimethoprim–sulfamethoxazole, it is often used in horses, dogs, and other species for oral administration. Many veterinarians consider trimethoprim–sulfamethoxazole to be interchangeable with trimethoprim–sulfadiazine. Although there are no side-by-side comparisons in clinical studies, there is no reason to doubt this assumption. For susceptibility testing, trimethoprim–sulfamethoxazole can be used as a surrogate to test susceptibility of trimethoprim–sulfadiazine. The pharmacokinetics have been examined in horses (Brown et al., 1988; Peck et al., 2002) (Table 32.4) and the pharmacokinetics are favorable for clinical use and dosage regimens that essentially mirror that of the use of trimethoprim–sulfadiazine.

Trimethoprim–Sulfachlorpyridazine

Even though this product is rarely used, the studies of trimethoprim–sulfachlorpyridazine have been primarily in horses. Horses given 5 mg/kg trimethoprim and 25 mg/kg sulfachlorpyridazine IV revealed an elimination half-life of 2.57 hours (trimethoprim) and 3.78 hours (sulfachlorpyridazine) and a volume of distribution of 1.51 l/kg (trimethoprim) and 0.26 l/kg (sulfachlorpyridazine) (van Duijkeren et al., 1995). Bioavailability of the same dose of sulfachlorpyridazine in a powder formulation administered in the feed was about 46%. The dose of trimethoprim–sulfachlorpyridazine of 30 mg/kg (combined drug) twice daily is recommended for most indications in horses (Van Duijkeren et al., 1995).

Sulfadimethoxine–Ormetoprim

Sulfadimethoxine has been formulated with ormetoprim to enhance the spectrum of antimicrobial activity in a similar manner to trimethoprim's enhancement of the activity of other sulfonamides. Commercial preparations of ormetoprim–sulfadimethoxine are available for dogs (Primor tablets), poultry (Rofenaid premix for feed), and for fish (Romet). These combinations offer the same advantages as trimethoprim–sulfonamide combinations because the ormetoprim component produces the same synergistic effect as trimethoprim. Pharmacokinetic parameters of ormetoprim are listed in Table 32.6.

Sulfadimethoxine–ormetoprim is available as a premix for medicated feed (Rofenaid). In this form, sulfadimethoxine–ormetoprim is used for prevention of coccidiosis in chickens and turkeys caused by susceptible *Eimeria* species and for prevention of fowl cholera. A similar formulation (Romet) also is available for treating furunculosis in salmon and trout. Sulfadimethoxine–ormetoprim oral tablets for dogs (Primor) have been used for skin and soft tissue infections, urinary tract infections, and intestinal coccidia infections. It has been administered once daily for these indications.

There are no commercially available cattle formulations of sulfadimethoxine–ormetoprim in the US However, this combination has been shown to be highly effective in treating calves with experimentally induced *Mannheimia hemolytica* pneumonia. Wilson et al. (1987) investigated the potential efficacy of a sulfadimethoxine–ormetoprim combination administered orally and IV to treat *Moraxella bovis* infections in cattle. In cattle, sulfadimethoxine–ormetoprim administered IV was effective in maintaining sufficiently high concentrations of both drugs in the tears to exceed the known MICs of 13 *Moraxella bovis* isolates and in maintaining those concentrations for approximately 6 hours. However, when the same concentration of sulfadimethoxine–ormetoprim was administered orally, sulfadimethoxine appeared in low concentrations and ormetoprim in very low or trace concentrations in the tears, indicating this combination of drugs when administered orally is not suitable for treating *Moraxella bovis* infections in cattle.

In horses, pharmacokinetics were described by Brown et al. (1989). That study administered sulfadimethoxine–ormetoprim (45.8 mg/kg:9.2 mg/kg) orally, followed by lower oral doses (22.9 mg/kg:4.6 mg/kg) at 24-hour intervals, to healthy adult mares. Sulfadimethoxine produced peak plasma concentrations 8 hours after the initial dose, and plasma concentrations above 50 μg/ml were maintained for the entire dosing schedule. Significant concentrations were also found in the synovial fluid, peritoneal fluid, endometrium, and urine, with a small amount (2.1 mg/ml) appearing in the cerebrospinal fluid approximately 100 hours after the initial dose.

The pharmacokinetic parameters of sulfadimethoxine–ormetoprim were determined in 1- to 3-day-old foals given a sulfadimethoxine–ormetoprim dose (17.5 mg/kg:3.5 mg/kg) orally (Brown et al., 1993). In the foals, sulfadimethoxine concentrations peaked at 8 hours (55 μg/ml) after the oral dose and declined to 37.6 μg/ml 24 hours after the dose.

Residues in Food Animals

Tissue residues from sulfonamide use in food-producing animals are a concern of both US government agencies and the end consumers (Bevill, 1989). FARAD (Food Animal Residue Avoidance Databank), a computerized databank of scientific and regulatory data, has specific information on the withdrawal times for sulfonamides used extralabel (www.farad.org) in food-producing animals (Riviere et al., 1986). Chapter 61 of this book address the issues of residues in food-producing animals. Detection methods for sulfonamides and metabolites have also been described (Sharma et al., 1976; Agarwal, 1992).

Sulfonamide residues were a problem in the United States for at least 30 years, having produced more drug-residue violations than any other drug, with the highest incidence occurring in pork, followed by veal and poultry. Residues in animal tissues consumed by humans are considered to be potential health hazards to humans. Toxic or allergic reactions to the sulfonamide class of antimicrobials have been reported in humans receiving therapeutic doses of sulfonamides. However, we are aware of no reports in the open literature about toxicity or other adverse reactions in humans consuming animal products containing trace amounts of sulfonamides or its metabolites. Evidence indicating that sulfonamides (in particular, sulfamethazine) may be carcinogenic in humans consuming small amounts over long periods of time (based on in vivo rat and mouse data) heightened the Food Safety Inspection Service's (FSIS) concern for controlling sulfonamide residues in food animals (USDA, 1988).

The highest rate of sulfonamide–residue violations has historically occurred in swine. Sulfamethazine and sulfathiazole are the two most commonly used sulfonamides in swine feeds today. However, sulfamethazine was responsible for most of the sulfonamide–residue violations (97%) because it had been commonly added to swine feeds and its longer half-life when compared to that of sulfathiazole (12.7 versus 1.2 hours). The primary reasons for the occurrence of violative levels of sulfonamides in pork were failure to observe drug withdrawal time, improper feed mixing, and improper cleaning of feed-mixing equipment, causing a cross-contamination of feed (Bevill, 1984, 1989). During the late 1970s, 13% of swine livers were found to be in violation of federal sulfonamide tissue concentrations. At that time the maximum amount of sulfonamide (parent compound) permitted in animal tissues was 0.1 ppm, with a 7-day withdrawal period. Drug manufacturers at this time increased the withdrawal time for sulfonamides used in animal feed from 7 to 15 days, and, by 1980, the violation rate in liver tissue had fallen to 4%. In 1987, the rate was reported to be 3.8% (Augsburg, 1989), with the rate decreasing significantly by the end of the 1990s. Part of the persistence of even these low levels may also be related to the ease of cross contamination seen after water medication (Mason et al., 2008).

In veal calves presented for slaughter, similar problems with sulfamethazine residues have been reported. The prevalence rate of sulfamethazine violations in veal calves was 1.9% in 1979 and 2.9% in 1981. Reasons for violations in this species include administering the drug to calves by individuals unaware of the drug withdrawal time constraints, unknowingly selling calves treated with sulfonamides, not following drug label directions, not seeking professional advice regarding drug use, and failing to maintain drug use records (Bevill, 1989).

Legal control of veterinary drugs is discussed in Chapter 55 of this book, and more information about residues in food-producing animals is presented in Chapter 61 of this textbook and also in previous editions. Several references are also available on this subject (Kaneene and Miller, 1992; Bevill, 1984; Dalvi, 1988; Rosenberg, 1985).

β-Lactam Antibiotics: Penicillins, Cephalosporins, and Related Drugs

Mark G. Papich

In 1928, Alexander Fleming observed that a *Penicillium* mold contaminating a Petri dish culture of staphylococci colonies was surrounded by a clear zone free of growth. Fleming cultured the contaminating mold on a special medium and demonstrated that the culture broth contained a potent antibacterial substance that was relatively nontoxic to animals, but was active against a variety of gram-positive organisms. He named the substance *penicillin*. In 1940, penicillin was isolated in the form of a brown, impure powder and was the most powerful chemotherapeutic agent known at that time. Since then, more than 40 penicillins have been identified. Some occur naturally; others are biosynthesized (semisynthetic penicillins).

In 1945, *Cephalosporium acremonium* was isolated from raw sewage. The first cephalosporin, cephalosporin C, was derived from this fungus. All other cephalosporins are semisynthetic antibiotic derivatives of cephalosporin C. The first cephalosporin was available for clinical use in 1964. Since those first cephalosporins, they have developed through first, second, third, and fourth generations, all of which are used in veterinary medicine. There is now a commercially available *fifth* generation used in humans. The reader may notice differences in spelling. The older cephalosporins, derived from the fungus are spelled *ceph*, whereas the newer semisynthetic derivatives are spelled *cef*.

Although penicillins, penicillin derivatives, and cephalosporins are still the most commonly used β-lactam antibiotics, much progress has been made in the development of new β-lactams during recent years. Most notably, these include the β-lactamase inhibitors (e.g., clavulanic acid), new cephalosporins, the carbapenems, also known as *penems* (e.g., imipenem, meropenem, ertapenem, doripenem), and the monobactams (e.g., aztreonam) (Abraham, 1987).

Mechanism of Action of β-Lactam Antibiotics

β-lactam antibiotics exert their effects by preventing bacterial cell wall synthesis and disrupting bacterial cell wall integrity. These drugs are considered *bactericidal* in a time-dependent manner. They kill bacteria by inhibiting or weakening the cell wall. The cell wall of bacteria consists of alternating units of *N-acetylglucosamine* and *N-acetylmuramic acid,* which are cross-linked by short strands of peptides. A transpeptidation reaction is responsible for cross-linking the strands to form a strong, netlike structure. Inhibition of this transpeptidation reaction by acetylating the enzyme is one of the sites of action for β-lactam antibiotics. Interference with transpeptidation results in a weak cell wall and rupture of the bacteria.

The binding sites for β-lactam antibiotics are called penicillin-binding proteins (PBPs), which are the enzymes that form the cell wall. There can be anywhere from two to eight distinct PBPs in bacteria, which are numbered according to their molecular weight. The most common PBPs affected by β-lactams are PBP-1, -2, or -3. Some of the variation in spectrum of action and bactericidal action of β-lactam antibiotics can be related to their relative affinity for different PBPs. For example, inhibition of PBP-1a and -1b generally cause lysis, PBP-2 results in rounded cells called *spheroblasts,* and PBP-3 produces long filamentous forms. The drugs that cause rapid lysis (for example, carbapenems) are the most bactericidal and have highest affinity for PBP-1.

On the other hand, mutations in the enzyme, produced by the resistance gene *mecA*, produces PBP-2a, a penicillin-binding protein that resists binding of the β-lactam drugs and renders bacteria with this gene resistant. The PBP-2a target is the basis for resistance to

Veterinary Pharmacology and Therapeutics, Tenth Edition. Edited by Jim E. Riviere and Mark G. Papich.

Companion Website: www.wiley.com/go/riviere/pharmacology

methicillin and oxacillin, known as *methicillin-resistant staphylococci (MRS)* (Weese, 2005).

In order to reach the site of action, these drugs first must penetrate the outer layer of the bacteria. They penetrate the outer layer of bacteria through a pore (a porin protein) that is ordinarily present in bacteria to allow nutrients to enter the cell. It is generally easier to reach the target site in gram-positive bacteria and they usually are more susceptible to the effects of β-lactam antibiotics than gram-negative bacteria. Gram-negative bacteria may have a thick outer membrane and have pores more difficult to penetrate. The drugs most effective against gram-negative bacteria are those that can rapidly penetrate the outer membrane of the cell wall.

Pharmacokinetic–Pharmacodynamic (PK-PD) Properties

The β-lactam antibiotics are time dependent in their activity (Turnidge, 1998). β-lactam antibiotics are slowly bactericidal because of the slow rate of acetylation of the PBP, and the time of drug concentration above the minimum inhibitory concentration (MIC) (T > MIC) is important to clinical success (Drusano, 2004). At low exposure of β-lactams, not all of the available PBP are acetylated and bacterial stasis occurs (bacteriostatic effect). As the maximum number of PBP become acetylated, bactericidal activity occurs. Once maximum acetylation of the enzymes occurs the killing rate does not increase further, which explains the time-dependent effect of β-lactams, rather than a concentration-dependent effect. In some cases, drug concentrations can fall below the MIC for treating staphylococcal infections and still attain a cure because of a postantibiotic effect (PAE), but a PAE does not occur against gram-negative bacilli (Zhanel et al., 1991). Additionally, since the MICs are lower for gram-positive bacteria, longer dose intervals may be possible for infections caused by gram-positive as compared to gram-negative bacteria because it is easier to keep the plasma concentration above the MIC.

The optimum duration of plasma concentrations above the MIC has varied among studies, but a general assumption is that the drug concentration should be above the MIC for 50% – and perhaps less – of the dosing interval (Turnidge, 1998; Drusano, 2004). This may vary depending on the immune competence of the animal and specific drug class. The carbapenem group of drugs (for example, imipenem and meropenem), are used with increasing popularity in small animal practice. These drugs are more bactericidal than penicillins and cephalosporins and the T > MIC for successful therapy may be less for these drugs than other β-lactams (for example, 30% of the dose interval). When immune competence is a question – for any of the β-lactams – increasing the time above MIC is advised.

Dosage regimens for the β-lactam antibiotics should consider these pharmacodynamic relationships. Therefore, for treating a gram-negative infection, especially a serious one, it is necessary to administer many of the penicillin derivatives and cephalosporins three to four times per day if they have short half-lives. Some of the third-generation cephalosporins have long half-lives and less frequent regimens have been used for some of these drugs (e.g., ceftiofur–Naxcel, cefovecin–Convenia, and cefpodoxime proxetil–Simplicef). For highly susceptible gram-positive infections, less frequent administration may be acceptable. Note that the indications on the FDA-approved label for veterinary β-lactams may be aimed at these highly susceptible gram-positive pathogens and may not be appropriate for gram-negative bacteria with higher MIC values. Specific examples to illustrate this point are provided in this chapter.

Microbial Resistance to β-Lactam Antibiotics

Three independent factors determine the bacterial susceptibility to β-lactam antibiotics: (i) production of β-lactamases, (ii) decreased penetration through the outer cell membrane to access the cell wall enzymes (which includes efflux pump mechanisms), and (iii) the resistance of the target (PBP) to binding by β-lactam agents (Gold and Moellering, 1996; Frere et al., 1991). An example of an altered target (PBP) is the one found in methicillin-resistant isolates, mentioned in Section Mechanism Of Action Of β-Lactam Antibiotics.

β-Lactamase Enzymes

The elaboration of β-lactamases, enzymes that inactivate the drugs by hydrolyzing the β-lactam ring, is the major mechanism of drug resistance (Jacoby and Munoz-Price, 2005). Bacteria produce β-lactamases that possess a range of physical, chemical, and functional properties. Some β-lactamases are specific for penicillins (penicillinases), some are specific for cephalosporins (cephalosporinases), and others have affinity for both groups.

The genes that code for β-lactamases can occur via mutations in chromosomes, or they may be transferred by genetic elements. The genetic elements carrying these genes – which may be transferred among bacteria – include plasmids, which may be organized into integrons or carried on tranposons. A transposon may move (transpose) from DNA to plasmids, and vice versa. Integrons may be part of a transposon. The integrons may also contain genes that code for resistance to other drugs – thus producing multidrug resistance.

There are many β-lactamase enzymes that are capable of hydrolyzing the cyclic amide bond of the β-lactam structure and inactivating the drug. Investigators have described over 190 unique β-lactamase proteins that have this ability. Classification schemes may vary, and β-lactamase enzymes have been categorized according to molecular structure and substrate, bacterial type (gram-negative versus gram-positive), transmission (plasmid coded versus chromosomal coded), and whether they are inducible or constitutive. The Ambler Class (Class A, B, C, and D), which uses amino acid sequencing, is now widely accepted (Rice and Bonomo, 2000; Jacoby and Munoz-Price, 2005). Class A enzymes are the most important in veterinary medicine. These include those listed in the following sections.

Staphylococcal β-Lactamase

These are produced by coagulase-positive *Staphylococcus* sp. and some coagulase-negative strains. The synthesis of these enzymes is determined by specific resistance genes and the enzymes are exocelluar. These enzymes typically do not inactivate cephalosporins and antistaphylococcal penicillins (e.g., isoxazolyl penicillins such as oxacillin or dicloxacillin). These β-lactamases can be inactivated by β-lactamase inhibitors (e.g., clavulanate acid, tazobactam, and sulbactam).

Gram-Negative β-Lactamases

This is a very diverse group that can arise through mutation or via transferable genetic elements. These enzymes are more wide spectrum and can hydrolyze penicillins (penicillinases), cephalosporins (cephalosporinases), or both. β-lactamases produced by Enterobacteriaceae such as *E. coli* belong to the TEM, SHV, and CTX-M, families, as well as other less common groups. Some, but not all, of these enzymes are inhibited by β-lactamase inhibitors (e.g., clavulanate, sulbactam). Gram-negative bacteria secrete small amounts of β-lactamases into their periplasmic space, allowing for optimal location of the enzyme to degrade the β-lactam upon entry into the organism. The advantage of newer drugs such as third-generation cephalosporins (also called *oxyimino-β-lactams*) and carbapenems is their ability to remain stable to gram-negative β-lactamases.

Among the most serious of the gram-negative β-lactamases are the ESBLs – extended-spectrum β-lactamases. These β-lactamases will cause resistance to even the most active (extended-spectrum) cephalosporins. These enzymes are generally acquired through horizontal gene transfer (plasmids or transposons), but resistant clones also can spread in the local environment or hospital. Regardless of the mechanism, it presents a challenge to clinicians. Bacteria positive for ESBL can be difficult to treat because of limited drug options, and many are resistant to other classes of antibiotics. A more recently emerging β-lactamase resistance is the production of carbapenemase. This enzyme will inactivate the valuable carbepenem class of drugs. These bacteria have been identified as *carbapenem-resistant Enterobacteriaceae* (CRE), and include the *Klebsiella pneumoniae* carbapenemase (KPC). Bacteria that carry this resistance are very difficult to treat because there are so few available treatment options. Fortunately, this mode of resistance has not yet become a clinical problem in veterinary medicine, but there are concerns about its occurrence in animals (Abraham et al., 2014).

Resistance Caused by Reduced Access to Binding Sites

Gram-negative bacteria can produce a cell wall with a modified outer membrane that is no longer permeable to β-lactam antibiotics. These impenetrable porin proteins can resist entry by β-lactam drugs. Reducing the permeability of the outer membrane limits antibiotic entry into the bacteria by down-regulation of the porin protein, or by replacement of the porin with a channel that resists entry by the drug. The porins can also delay or slow the rate of entry, thus making the drugs more susceptible to attack by β-lactamase enzymes. Therefore, this mechanism can enhance resistance produced by the elaboration of β-lactamases.

Another mechanism that inhibits access to target sites is the efflux of β-lactams out of the bacteria. This mechanism actively transports the antibiotic out of the cell. When these pumps are expressed, it can produce a high level of resistance and can affect multiple drug classes – thus conferring multidrug resistance (MDR). The MDR efflux pumps may be carried on chromosomes or transferred by plasmids.

Penicillins

General Pharmacology

Penicillin G is historically important because it was the first antibiotic introduced in medicine. Alexander Fleming discovered penicillin in 1928, but it was not used clinically until the early 1940s. Much of the early supply was designated for military use during World War II. It remains a popular antibiotic and is still the drug of choice for initial treatment of many infections in horses and cattle. It has little usefulness in small animals because of the high incidence of resistance.

Unitage

Penicillin is one of the few antibiotics that is still measured in terms of units rather than weight in mg or μg. One unit of penicillin represents the specific activity in

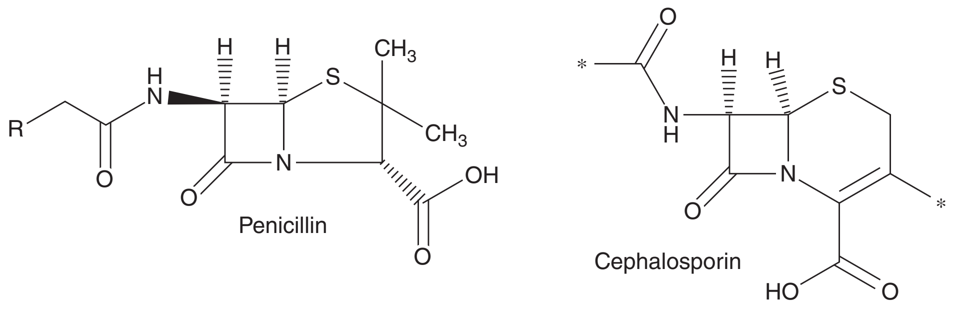

Figure 33.1 Structure of penicillins (left) and cephalosporins (right). Penicillins are composed of a five-member thiazolidine ring; cephalosporins are composed of a six-member dihydrothiazine ring. The structures can be modified into different drugs by replacing the R-groups or asterisk (∗) with other functional groups. The most critical feature of the structure to exert its antibacterial action is the β-lactam ring. If the β-lactam ring is broken (hydrolyzed), the drug is inactive.

0.6 μg of sodium penicillin based on the International Standard for Penicillin. Thus, one mg of penicillin sodium represents 1,667 units of penicillin. Doses of other β-lactams are expressed in weight (mg) rather than units.

Structure

Penicillin contains a fused ring system, the β-lactam thiazolidine (Figure 33.1). The physical and chemical properties, especially solubility, of penicillins are determined by the acyl side chain and the cations used to form salts.

Hydrolysis is the main cause of penicillin degradation, which can occur via bacterial enzymes (β-lactamases). This reaction also can occur from drug interactions (for example, in the syringe when penicillin is mixed with another drug). Some penicillins are poorly orally absorbed because they are unstable in the stomach and hydrolyzed by gastric acid. Penicillin is incompatible with heavy metal ions, oxidizing agents, and strong concentrations of alcohol.

The penicillins are listed in categories based on their synthesis and spectrum of action. These include the natural penicillins (e.g. penicillin G), aminopenicillins (e.g. ampicillin, amoxicillin), antistaphylococcal penicillins (e.g. oxacillin), and the extended-spectrum penicillins (e.g. piperacillin). These are discussed in more detail in specific sections later in the chapter.

Antimicrobial Activity

The natural penicillins are active against many *Streptococcus* spp. and nonpenicillinase-producing *Staphylococcus* spp. They are active against some gram-positive, but only selected gram-negative bacteria, which include *Arcanobacterium* (formerly *Actinomyces*), *Listeria monocytogenes,* and *Pasteurella multocida*. Therefore, these drugs are narrow-spectrum drugs that are active against non–β-lactamase–producing gram-positive bacteria but few gram-negative bacteria. Many anaerobic bacteria are susceptible, including *Fusobacterium, Peptococcus, Peptostreptococcus*, and some strains of *Bacteroides* (except *Bacteriodes fragilis* group) and *Clostridium.* These drugs are also active against most spirochetes, including *Leptospira* and *Borrelia burgdorferi*. Natural penicillins are consistently inactive against *Pseudomonas*, most Enterobacteriaceae, and penicillinase-producing *Staphylococcus* spp.

Aminopenicillins are active against the bacteria that are susceptible to penicillin G. They can penetrate through the outer membrane of gram-negative bacilli better than penicillin, which increases the spectrum to include some Enterobacteriaceae, including strains of *E. coli, Proteus mirabilis*, and *Salmonella;* however, most are resistant. Aminopenicillins are inactive against *Pseudomonas, Bacteroides fragilis*, and penicillinase-producing *Staphylococcus* spp. There are only subtle differences in antimicrobial activity between amoxicillin and ampicillin, and for susceptibility testing purposes, they are considered equivalent (CLSI, 2015).

The antistaphylocccal penicillins include methicillin and nafcillin as well as the isoxazolylpenicillins (oxacillin, cloxacillin, and dicloxacillin). The isoxazolylpenicillins are considered as a group because of their structural similarity. These semisynthetic penicillins are active against many penicillinase-producing *Staphylococcus* spp. that would ordinarily be resistant to penicillin G and the aminopenicillins. They also have some activity against other gram-positive and gram-negative bacteria and spirochetes. They are rarely, if ever, used clinically except for intramammary products that contain cloxacillin.

The extended-spectrum penicillins have the most activity against gram-negative aerobic and anaerobic bacteria of all of the penicillin groups. The drugs are active against many strains of Enterobacteriaceae and some strains of *Pseudomonas*. Carbenicillin and ticarcillin are active against some strains of *E. coli, Morganella morganii, Proteus* spp., and *Salmonella*. In addition to these organisms, mezlocillin and piperacillin are active against some strains of *Enterobacter, Citrobacter, Klebsiella*, and *Serratia*. These extended-spectrum penicillins have some activity against gram-positive aerobic and anaerobic bacteria but have no advantages against these organisms compared to penicillin G and aminopenicillins. Extended-spectrum penicillins are generally more active against *Bacteroides fragilis* than are other available penicillins. Of this group, few are available and used clinically. Ticarcillin and ticarcillin–clavulanate, once popular for injectable use, is no longer available. Carbenicillin is no longer available. Piperacillin–tazobactam is the most popular and widely available of this group.

Susceptibility Testing

The CLSI has approved breakpoints for animals for most of the penicillins and derivatives (CLSI, 2013, 2015). These breakpoints often reflect the accepted clinical use of the drug and not necessarily the approved label indication. For example, the breakpoint for procaine penicillin G was established using a dose of 22,000 U/kg IM, consistent with good clinical practice, rather than the FDA-approved label dose of 7,500 U/kg. CLSI approved breakpoints are listed in Table 33.1.

Pharmacokinetics

Ampicillin and amoxicillin have been the most studied of the penicillin group and Table 33.2 lists the pharmacokinetic parameters in several domestic species. Penicillin G pharmacokinetics are presented in Table 33.3. When sodium salts of these drugs are injected, maximum blood concentrations occur usually within an hour.

Absorption

For the penicillin G formulations, distinct absorption patterns are observed, depending on which form is administered, the formulation, and the site of injection. The long-acting formulations (procaine- or benzathine–penicillin) are given IM or SC (never IV). The slow absorption from the injection site prolongs the plasma concentration. Injections of penicillin G IM to horses produced prolonged plasma concentrations, even when the sodium salt of penicillin was administered (Uboh et al., 2000). The half-life was longer from the procaine formulation, but at 24 hours, concentrations were similar in horses, regardless of whether the procaine or potassium formulation of penicillin G was administered. Benzathine formulations produce lower, but much longer, plasma concentrations because of insolubility and extremely slow absorption from the injection site (Papich et al., 1994).

For all the penicillins, as expected, the maximum plasma concentration will be lower, and the time to reach maximum concentration delayed, from an IM route versus IV route. More rapid absorption occurs from IM injection than SC. Also, there are differences depending on the location in large animals, with an injection in the neck muscle being absorbed faster than an injection in gluteal muscle (Papich et al., 1993). This pattern of absorption has been shown for other penicillins in cattle and horses (Firth, 1986), in which injections in the neck muscle are absorbed more rapidly and completely than injections in the rear leg.

For ampicillin and amoxicillin, these can be administered IM or IV as sodium salts, or they may be formulated as the trihydrate form that is more stable in aqueous solutions and may be administered SC or IM to produce a more prolonged absorption phase and a longer duration of activity (Traver and Riviere, 1982). Sodium salts of the other penicillin derivatives are no longer commercially available for IM or IV administration (e.g., ticarcillin sodium, piperacillin sodium, etc.).

Penicillin is easily inactivated in the acidic pH of the stomach (a pH of 6–6.5 is optimum for chemical stability), and therefore is not absorbed orally (except the acid-stable penicillin V, which is discussed under the specific formulations below). Because oral absorption of penicillin G is not sufficient to be of therapeutic value in animals this route is not used.

Amoxicillin and ampicillin are often administered to small animals. Amoxicillin differs from ampicillin only by the addition of a hydroxyl group (Figure 33.2). This decreases the lipophilicity of amoxicillin, but increases the oral absorption, whereby systemic availability of amoxicillin administered orally is higher than a similar dose of ampicillin (Watson et al., 1986). For example, absorption of ampicillin in dogs and cats has been reported to range from 30 to 40%, and for amoxicillin 64 to 68% (Küng and Wanner, 1994). Ampicillin had wide variation of oral absorption in cats (18% for suspension; 42% for capsule), depending on the dosage form (Mercer et al., 1977). Amoxicillin also has twice the systemic bioavailability of ampicillin when administered orally in pigs and preruminant calves. Other penicillin derivatives may have low oral absorption, which limits their clinical usefulness. Cloxacillin is absorbed poorly in dogs (Watson et al., 1986; Dimitrova et al., 1998) and with its short half-life is unsuitable for therapy in dogs.

The effect of feeding on oral absorption of these drugs has been debated, and results have varied, depending on the conditions of the study. The most complete study on this subject was reported by Watson et al. (1986). They found that feeding dogs inhibited oral absorption of amoxicillin, ampicillin, penicillin V, and cloxacillin. The effect was modest for ampicillin and amoxicillin (feeding decreased ampicillin tablets by 38%, but only 20–25% for amoxicillin). Feeding had a large effect for cloxacillin, decreasing oral absorption by 74%.

Aminopenicillins are absorbed poorly in horses and ruminants following oral administration.

Table 33.1 Susceptibility breakpoints for penicillin and derivatives (as approved by CLSI, 2013, 2015).

Species	Body site	Antimicrobial agent	MIC interpretive criteria (µg/ml) S	I	R	Comments
Dogs	Skin, soft tissue (*E. coli*)	Ampicillin	≤ 0.25	0.5	≥ 1.0	Ampicillin may be used to test for amoxicillin. Systemic breakpoint derived from microbiological, PK-PD data. For dogs, the dose of amoxicillin was 22 mg/kg every 12 hours orally.
Dogs	Skin, soft tissue (gram-positive cocci)	Ampicillin	≤ 0.25	–	≥ 0.5	Ampicillin is used to test for susceptibility to amoxicillin and hetacillin. Systemic breakpoint derived from microbiological, PK-PD data. For dogs, the dose of amoxicillin was 22 mg/kg every 12 hours orally.
Dog	UTI	Ampicillin	≤8	–	–	A breakpoint of ≤8 can be used for uncomplicated UTI to account for high concentration in urine.
Dogs	Skin, soft tissue	Amoxicillin–clavulanate	≤0.25/ 0.12	0.5/0.25	≥1/0.5	Amoxicillin–clavulanate breakpoints were determined from an examination of MIC distribution of isolates, efficacy data, and PK-PD analysis of amoxicillin in dogs. The dosage regimen used for PK-PD analysis of amoxicillin was 11 mg/kg administered every 12 hours orally.
Dogs	UTI	Amoxicillin–clavulanate	≤8/4			A breakpoint of ≤8/4 can be used for uncomplicated UTI to account for high concentration in urine.
Dogs	Skin, soft tissue, UTI	Piperacillin–tazobactam	≤8/4	≤16/4	≤32/4	Breakpoint was derived from an examination of MIC distribution data, and PK-PD analysis of piperacillin in dogs at a dosage of 350 mg/kg every 6 hours, intravenously, or 3.2 mg/kg/hour constant rate IV infusion.
Cats	Skin, soft tissue, UTI	Amoxicillin–clavulanate	≤0.25/ 0.12	0.5/0.25	≥1/0.5	Amoxicillin–clavulanic acid breakpoints were determined from an examination of MIC distribution of isolates, efficacy data, and PK-PD analysis of amoxicillin in cats at a dosage of 12.5 mg/kg (amoxicillin) administered every 12 hours orally.
Horse	Respiratory, soft tissue	Penicillin G	≤ 0.5	1	≥ 2	Breakpoints derived from microbiological, PK data (using accepted clinical, but extralabel doses), and PD data. The dose of procaine penicillin G modeled was 22000 U/k, IM, every 24 hours.
Horse	Respiratory Disease	Ampicillin	≤ 0.25	–	–	For strains yielding results suggestive of a "nonsusceptible" category, organism identification and antimicrobial susceptibility test results should be confirmed.
Swine	Lung (SRD)	Ampicillin	≤ 0.5	1	≥ 2	Breakpoints derived from microbiological data using ampicillin, PK data from a dose of 15 mg/kg IM of amoxicillin once daily, and PD data.
Swine	Lung (SRD)	Penicillin G	≤ 0.25	0.5	≥ 1	Breakpoints derived from microbiological, pharmacokinetic data (using accepted clinical, but extralabel doses), and pharmacodynamic data. The dose of procaine penicillin G modeled was at a dose of 33,000 U/kg, IM by needle in the neck, every 24 hours.
Cattle	Lung (BRD)	Penicillin G	≤ 0.25	0.5	≥ 1.0	Breakpoints derived from microbiological, PK data (using accepted clinical, but extralabel doses), and PD data. The dose of procaine penicillin G modeled was 22000 U/k, IM, every 24 hours.
Cattle	Mastitis	Penicillin–novobiocin	≤ 1/2	2/4	≥4/ 8	Mastitis use only.

BRD, bovine respiratory disease; SRD, swine respiratory disease; PK, pharmacokinetic; PD, pharmacodynamic; R, resistant; I, intermediate; S, susceptible; UTI, urinary tract infection.

[a] Craigmill et al. (2004). Craigmill's analysis used 18 published papers, 28 data sets, and 288 data points. They also reported a volume of distribution/F of 13 l/kg (± 7.46).

[b] Mean values (± standard deviation) is available for more than one study.

They can be absorbed in preruminant calves, but not ruminating (6 weeks of age) calves (Soback et al., 1987a). Oral absorption of ampicillin in adult horses has been reported to be only 2–3.5% (Ensink et al., 1996; Sarasola and McKellar, 1994). Systemic availability of oral amoxicillin is higher than ampicillin in adult horses but is only 2–10% (Wilson et al., 1988; Ensink et al., 1992, 1996; Baggot, 1988; Sarasola and McKellar, 1994); still too low to be practical for dosing. In foals, oral absorption of amoxicillin has been higher at 36.2–42.7% (Baggot et al., 1988), but this is a seldom-used route of administration.

Elimination

The elimination half-life for IV penicillin is short (0.5 to 1.2 hours). Slow-release formulations are designed to lengthen this half-life. For example, because of slow release from the injection site, procaine penicillin may produce a terminal half-life of 20 hours or more and can maintain concentrations against susceptible bacteria for 24 hours after a single injection. The prolonged terminal half-life is caused by slow absorption (see the Section Absorption), rather than slow elimination, which is referred to as the "flip-flop effect" determining the plasma profile. All penicillins rely on renal elimination (primarily tubular secretion) and reach high drug concentrations in the urine.

Distribution

Penicillins diffuse into extracellular fluid easily unless protein binding is high. Protein binding is low to moderate in most species, ranging from approximately 30 to

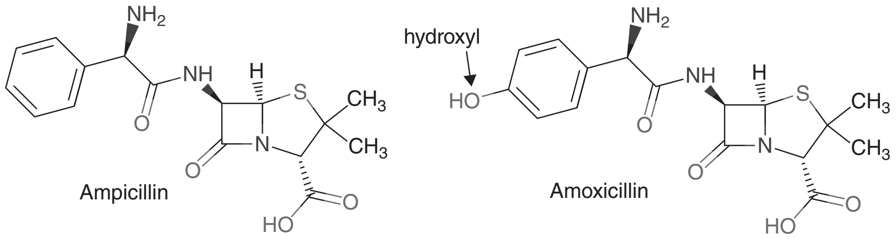

Figure 33.2 Structure of ampicillin (left) and amoxicillin (right).

60%. Penicillin is a weak acid with a pK_a of 2.7, therefore it is mostly ionized in the plasma and the volume of distribution is moderate. For example, volume of distribution (Vd) listed in some studies is 0.2 to 0.3 l/kg. In some studies, and in some species, however, it may be as high as 0.6 to 0.7 l/kg. These values represent a distribution to extracellular fluid, and possibly reaching moderate intracellular concentrations. Sufficient concentrations are attained for susceptible bacteria in kidneys, synovial fluid, liver, lung, skin, and soft tissues (Stover et al., 1981; Brown et al., 1982; Beech et al., 1979). Penicillins do not penetrate the blood–brain barrier to reach concentrations in the central nervous system (CNS) to a large extent, but they have been used to treat infections of the CNS when administered at high doses.

Metabolism

Penicillin G, penicillin V, nafcillin, ticarcillin, and the aminopenicillins are metabolized to some extent by hydrolysis of the β-lactam ring. The metabolites are microbiologically inactive. Penicillins and their metabolites are excreted in the urine by tubular secretion. Most of the drug is excreted in the urine within 1 hour of IM injection of sodium or potassium penicillin in aqueous solution. Probenecid competitively inhibits renal tubular secretion of penicillins and can prolong the half-life of penicillin. However, probenecid is rarely used for this purpose in clinical situations.

Summary of Penicillins and Derivatives

Natural Penicillins

The only natural penicillins still in use are penicillin G and penicillin V. Penicillin V has a phenoxymethyl group that provides more acid stability in the stomach, allowing for oral administration. It has been used orally in people, but it is of limited value in animals. It had low oral absorption and limited spectrum in calves (Soback et al., 1987b). In dogs, oral administration of penicillin V tablets produces maximum plasma concentrations of 3.5–4.8 μg/ml, but the concentrations decline quickly and were above 0.5 μg/ml for only approximately 3 hours (Watson et al., 1987a, 1987b).

Penicillin formulations: There are three injectable formulations. Pharmacokinetics of these formulations are provided in Table 33.3:

1) *Na^+ and K^+ salts of penicillin, also called crystalline penicillin:* These are water soluble solutions and may be injected intravenously (IV), intramuscularly (IM), or subcutaneously (SC). They achieve rapid, but short-lived, plasma concentrations.
2) *Procaine penicillin G (Crysticillin, Pen-Aqueous):* This compound is a poorly soluble salt in an aqueous vehicle suspension that is slowly absorbed following intramuscular (IM) or subcutaneous (SC) injection. *Do not administer IV.*
3) *Benzathine penicillin G (Benza-pen, Durapen, Flo-cillin):* This preparation is the so-called "long-acting penicillin". It is absorbed more slowly than the procaine salt because of its insolubility. It produces persistent, but low, plasma concentrations. Most formulations of long-acting penicillin contain 50% procaine penicillin G, and 50% benzathine penicillin G. *Do not administer IV.*

Additional formulations and route of administration are the formulations of penicillin G administered via intramammary routes to treat bovine mastitis.

The doses of penicillin G vary greatly depending on the formulation, the species of animal, and the disease treated. It is best to consult references related to the specific disease being treated. In general, Na^+ or K^+ penicillin G are administered IM, or IV at doses of 20,000 to 50,000 U/kg every 4 to 6 hours. Procaine penicillin G is administered IM or SC at dosages of 22,000 to 70,000 U/kg, every 12 to 24 hours. Treatment of streptococcal infections may use a lower dose, but for some infections such as those caused by *Arcanobacterium* (formerly called *Actinomyces*) doses as high as 100,000 U/kg have been recommended.

The United States FDA–approved label dose for cattle is 7,500 U/kg, but the approved withdrawal time for food animals – 10 days – applies only to an approved food animal dose. Since the doses used in food animals are extralabel, extended withdrawal times must be applied. Food animal residues and withdrawal times are discussed further in Chapter 61 of this book.

Aminopenicillins

Ampicillin and amoxicillin have been used in the treatment of a variety of diseases in domestic animals. The half-life of all aminopenicillins is short (Table 33.2), requiring frequent administration for some infections, particularly gram-negative pathogens that may have high MIC values.

Aminopenicillins are popular because they have a broader spectrum of activity compared to penicillin G, can be administered orally, and are relatively inexpensive and safe. The aminopenicillins differ from penicillin by the addition of an amino group, and amoxicillin has a parahydroxy group that ampicillin lacks. Compared to penicillin G, these compounds have two ionization points (pK_a 2.7 and 7.3). Ampicillin is more soluble than amoxicillin, and is also more lipophilic (Log P ampicillin 1.35; Log P amoxicillin 0.87), but amoxicillin is better absorbed by a factor of approximately two in most animals.

Compared to penicillin G, the aminopenicillins can penetrate the outer layer of gram-negative bacteria better than penicillin G; therefore, they have a spectrum of activity that includes those listed for penicillin but is extended to include some of the gram-negative bacteria (e.g., susceptible Enterobacteriaceae). However, acquired resistance can be common and this group is still quite susceptible to β-lactamase. To overcome resistance the β-lactamase inhibitors clavulanic acid and sulbactam have been added to amoxicillin (Clavamox) and ampicillin (Unasyn), respectively, to increase the spectrum. These are discussed in section β-Lactamase Inhibitors.

Aminopenicillin formulations: The formulations of aminopenicillins used in veterinary medicine (examples of brand names in parentheses) that are available include:

1) *Sodium ampicillin:* This formulation is used for injection IM, IV, SC (Omnipen®).
2) *Ampicillin trihydrate (Polyflex®):* This is a poorly soluble, slow-release aqueous suspension. Absorption of this formulation is erratic, and it produces prolonged, but low, blood concentrations.
3) *Amoxicillin trihydrate:* (Amoxi-inject®).
4) *Ampicillin:* These are oral products such as tablets, capsules, and liquid suspensions (for example, Omnipen®).
5) *Amoxicillin:* These are oral products, such as tablets and liquids (Amoxi-Tabs®, Amoxi-Drops®, and others).
6) *Intramammary preparations:* These include Amoxi-Mast, which is used for treating mastitis.

The elimination of the aminopenicillins is slightly longer than that reported for sodium salts of penicillin, but this difference does not appear to relate to a difference in clinical efficacy. Common doses are listed in Table 33.4, and listed for breakpoints in Table 33.1. A common formulation used in animals is ampicillin trihydrate (Polyflex), a poorly soluble preparation. After IM injection, the half-life is 6.7 hours in cattle, which is adequate for once-daily administration (Gehring et al., 2005). The IM injection route in horses also prolongs the plasma concentration (Table 33.2).

Table 33.4 Common dosages for ampicillin and amoxicillin

Drug	Dose and species
Amoxicillin oral	Dogs, cats 6.6–20 mg/kg q 8–12 h
Ampicillin trihydrate injection	Cattle 6.6–22 mg/kg q 8, 12, or 24 h (24 h most common); the approved label dose in cattle is 4.4–11 mg/kg IM, q 24 h Dogs, cats: 10–20 mg/kg, q 12–24 h, IM, SC
Ampicillin sodium	Horses IV 10–20 mg/kg q 6–8 h
Ampicillin sodium	Horses IM 10–22 mg/kg q 12 h
Ampicillin sodium	Dogs, cats: 10–20 mg/kg, q 8 h, IV, IM, or SC

An important difference between the aminopenicillins and penicillin G is that the aminopenicillins are not inactivated by gastric acid and may be administered orally. There appears to be a saturable transport process for absorption of aminopenicillin in the intestine. Oral absorption of the penicillins in various species and effect of feeding and age is discussed in the Section Absorption.

In addition to the formulations listed above, there are ester derivatives of ampicillin, but these are not currently available. The advantage of these esters is that they are stable in the gastrointestinal tract and are absorbed intact, but esterases release the active drug after absorption across the intestinal mucosa. They are absorbed much better than the parent drugs. Examples of these drugs are *pivampicillin* and *bacampicillin* (Sarasola and McKellar, 1994; Ensink et al., 1996).

Antistaphylococcal Penicillins

Also called the β-lactamase stable penicillins, this group of antibiotics includes the isoxazolylpenicillins (e.g., oxacillin, cloxacillin, and dicloxacillin) and synthetic derivatives of penicillin (e.g., methicillin and nafcillin). These drugs are rarely used clinically in veterinary medicine (except for intramammary forms). These drugs have the disadvantage of poor or inconsistent oral absorption in animals and short half-life. More details on these drugs are provided in earlier editions of this book. They are resistant to the β-lactamase of *Staphylococcus* spp. They have minimal activity against gram-negative bacteria because they do not exhibit good penetration of the outer layer of these bacteria.

One of the drugs in this group is methicillin. If *Staphylococcus* shows phenotypic resistance to methicillin, it is a marker for resistance mediated by the *mecA*-gene, which codes for a resistant PBP protein. When it occurs in *S. aureus*, this type of resistance is called *methicillin-resistant Staphylococcus aureus*–MRSA. If the organism is *Staphylococcus pseudintermedius*, it is referred to as MRSP. Today, oxacillin is used to test for this resistance, even though the resistant strains are still referred to as "methicillin-resistant" (CLSI, 2013).

Preparations available: The only drug from this group that is used clinically is cloxacillin, which is used to treat staphylococcal and streptococcal mastitis. It is also available as an intramammary infusion for dry cows (cloxacillin benzathine).

Extended-Spectrum Penicillins

The extended-spectrum penicillins have also been called the *antipseudomonas penicillins* because they are among the few drugs active against *Pseudomonas*. This group includes the carboxypenicillins – carbenicillin and ticarcillin – because of a substitution of a carboxy group for the amino group on ampicillin, and the ureidopenicillins, which include piperacillin and azlocillin. The carboxy group decreased activity against *Streptococcus*, but improved penetration through the outer cell membrane of gram-negative bacteria. Substitution of a ureido for the carboxy group produced ureido penicillins, which maintained ampicillin's activity against *Streptococcus* and also produced good penetration through the outer membrane of gram-negative bacteria.

The value of this group of penicillins, particularly the ureidopenicillins, is their broad-spectrum activity and that they are able to penetrate the outer wall of *Pseudomonas* and some other gram-negative bacteria (e.g., *Proteus*, *Providencia*, and *Enterobacter*) better than other penicillins. Like the other penicillins, they are susceptible to β-lactamase inactivation, but the addition of tazobactam to piperacillin reduces this inactivation (discussed further in Section β-lactamase Inhibitors). This group has good synergistic activity when administered with the aminoglycosides (e.g., gentamicin, amikacin). The ureido penicillins also have good activity against anaerobic bacteria, and piperacillin may have some activity against enterococci.

Pharmacokinetic features: Despite advantages listed above, the disadvantage of this group of penicillins is the short half-life, which necessitates frequent administration. The half-life of these drugs is approximately 1 hour or less in most animals (VanCamp et al., 2000; Garg et al., 1987; Tilmant et al., 1985). The apparent volume of distribution is between 0.2 and 0.4 l/kg for most drugs in this class, much like other penicillins.

Clinical use: Ticarcillin and ticarcillin–clavulanate (Timentin®) was once a popular injectable antibiotic used in veterinary medicine and there was a formulation used in horses as an intrauterine flush diluted in saline (VanCamp et al., 2000). However, ticarcillin and the combination with clavulanate are no longer commercially available. Likewise, there are no longer formulations of carbenicillin available. More details about both of these drugs can be found in earlier editions of this book.

One drug from this group that still remains commercially available is piperacillin–tazobactam. (Piperacillin as a single agent is not available.) Piperacillin–tazobactam is discussed in more detail with the β-lactamase inhibitors.

Adverse Effects

Penicillins are very safe drugs, with relatively few adverse effects reported. Like most β-lactams, adverse effects are rare. The most common, and often most serious, adverse effects are attributed to allergy – immune-mediated reactions or allergic reactions. These are common in people from penicillins (approximately 15% of the human population) and are seen in veterinary species. Treatment may require administration of medications to attenuate the allergic response and avoidance of future use. Coombs-positive hemolytic anemia has been reported in horses following penicillin administration (Blue et al., 1987; Step et al., 1991).

After oral administration, there can be disruption of intestinal bacteria. *Clostridium* bacterial intestinal overgrowth from oral administration is a risk in guinea pigs, hamsters, gerbils, and rabbits.

Central nervous system reaction can be produced by penicillins (and other β-lactam antibiotics). At high concentrations these drugs can inhibit GABA (an inhibitory neurotransmitter) and cause excitement and seizures. Procaine, which is in some preparations, also causes excitement in some animals (horses) (Neilsen et al., 1988). There may be free procaine in some formulations of aqueous procaine penicillin G. When injected IM (or inadvertently IV) it can elicit an excitatory response. Because procaine can mask pain, and produce excitation in horses, its use is regulated in racing horses (see Chapter 57 on control of drugs in racing animals for additional information). Injections of procaine-penicillin in a horse may cause a positive procaine test reaction at the race track for as long as 2 weeks. Oral administration of ampicillin, amoxicillin, and similar formulations may cause vomiting at high doses.

Special Species Considerations

The penicillins are excreted similarly in all mammalian animals. In general, doses and intervals are similar among mammals, except that in larger species, dose intervals may be longer because of slower renal clearance. Renal clearance can be scaled allometrically to show that the larger body weight is associated with slower renal clearance.

In reptile species, clearance of all penicillin drugs is slow. The half-lives are much longer in reptiles, which allows for infrequent dosing intervals of once every 3–5 days. In birds, renal clearance and metabolic rate is high. This difference results in high doses and frequent intervals. Because of the need for frequent dosing, and because injectable drugs of this group may cause intramuscular pain, these drugs may be impractical in most clinical situations involving birds.

β-Lactamase Inhibitors

The β-lactamase inhibitors are a specific class of drugs with little antibacterial effects of their own, but they act

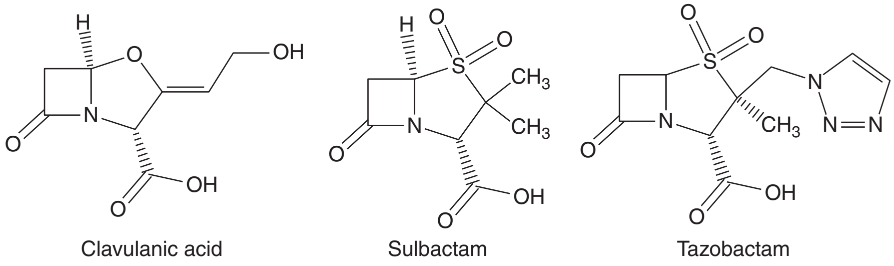

Figure 33.3 β-lactamase inhibitors: Structure of clavulanic acid (left), sulbactam (center), and tazobactam (right).

to inhibit the β-lactamase enzyme. They have structures that resemble the β-lactam antibiotics with an intact β-lactam ring structure (Figure 33.3). They are always combined with another active drug of the β-lactam class. These combinations, particularly amoxicillin–clavulanate, have been popular in veterinary medicine (Mealey, 2001). The primary drugs of this group are clavulanic acid (also called *potassium clavulanate*), combined with amoxicillin, sulbactam (combined with ampicillin), and tazobactam (combined with piperacillin).

Mechanism of Action

The β-lactamase inhibitors produce antibacterial effects only at high concentrations (Díez-Aguilar et al., 2015). They bind to the β-lactamase enzyme that is produced by gram-negative or gram-positive bacteria. This usually is an irreversible, noncompetitive binding. Clavulanate is considered an irreversible, suicide inhibitor. A wide range of β-lactamases are inhibited by clavulanate, including class B β-lactamases, TEM and SHV enzymes found in Enterobacteriaceae, many of the extended-spectrum β-lactamases, and various chromosomally mediated enzymes (Finlay et al., 2003). AMP-C β-lactamases are usually not inactivated by these agents.

When an inactive enzyme complex is formed from these inhibitors, the coadministered antibiotic (e.g., amoxicillin or ampicillin) can exert its antibacterial effect. All β-lactamase inhibitors are not equal with respect to potency and ability to bind β-lactamase enzymes. For example, compared to clavulanate, sulbactam is less active against β-lactamase of *Staphylococcus*, *Bacteroides,* and some *E. coli*. However, whether these differences are important clinically is not known.

Pharmacokinetics

The pharmacokinetics of clavulanate in animals has been studied more than the other inhibitors (Bywater et al., 1985; Vree et al., 2003). Clavulanate is notoriously unstable and should be protected from moisture. Tablets are packaged in foil-protective packaging. Although clavulanate is absorbed orally (the only one of the β-lactamases absorbed orally), the absorption is variable and can vary highly among animals administered similar doses (Vree et al., 2003). There is evidence that high doses of amoxicillin inhibit the absorption of clavulanate in dogs and people (Vree et al., 2003). Clavulanate is susceptible to enzymatic degradation and is excreted by glomerular filtration, whereas amoxicillin is eliminated by renal tubular excretion.

Examples and Clinical Use

Amoxicillin–clavulanic acid (Clavamox®, Synulox): This is one of the most popular oral antibiotics used in small animals. Amoxicillin–clavulanate, sometimes called potentiated amoxicillin and co-amoxiclav, extends the spectrum of amoxicillin to include many of the β-lactamase–producing bacteria. There is an equivalent drug used in people (Augmentin), which is one of the most popular drugs in human medicine. The human drug is not entirely equivalent because the proportion of amoxicillin: clavulanate may be different. Clavamox has a 4 : 1 ratio, whereas augmentin is either in a 4 : 1 ratio or a 7 : 1 ratio, depending on the tablet size. The dose administered to animals is a fixed ratio of 4 : 1 (amoxicillin : clavulanate), but because of lower absorption of clavulanate and more rapid excretion, the ratio in the body can be highly variable and as low as 20 : 1. For susceptibility testing, CLSI (CLSI, 2015) uses a fixed ratio of 2 : 1 (amoxicillin : clavulanate) (Table 33.1).

In small animals Clavamox® has been used to treat infections in almost all tissues (except CNS). It has been successful for skin infections and urinary tract infections (Bywater et al., 1985; Senior et al., 1985; Weese et al., 2011; Hillier et al., 2014). It is particularly useful to treat infections caused by β-lactamase–producing staphylococci. Amoxicillin–clavulanate also is useful for treating anaerobic infections in dogs and cats, such as those of the oral cavity (Indiveri and Hirsh, 1985).

In large animals, amoxicillin–clavulanate has not been an important drug. As reported previously, the oral absorption of amoxicillin in horses is small and unlikely to reach therapeutic concentrations. The oral administration has also been examined in calves (Soback et al., 1987a). There is sufficient absorption of amoxicillin–clavulanate in preruminant calves, but three-times-daily administration was recommended (Soback et al., 1987a), which is impractical. Oral absorption was not high enough in ruminant calves – because of degradation in the rumen – to produce therapeutic concentrations.

Sulbactam–ampicillin (Unasyn®): This is a human drug, but veterinary preparations exist in other countries. This drug has been administered IM, IV, and SC to dogs, cats, horses, and cattle. (Sulbactam is not absorbed orally.) In some countries (e.g., Canada) this combination is used as an intramuscular drug (ampicillin trihydrate + sulbactam, Synergistin) in cattle for the treatment of diseases such as pneumonic pasteurellosis (Risk and Bentley, 1987; Risk and Cummins, 1987; Girard et al., 1987).

Ticarcillin–clavulanic acid (Timentin®): This product is no longer available. Information about this preparation may be found in earlier editions of this book.

Piperacillin–tazobactam (Zosyn®, also referred to as "Pip-Taz"): This is one of the most popular intravenous (IV) antibiotics for in-hospital use in people. Piperacillin is an extended-spectrum penicillin and tazobactam has essentially the same activity as clavulanate. The use includes septicemia, urinary tract infections, skin, soft-tissue, respiratory infections, intraabdominal infections, and gynecological infections. Targeted organisms include bacteria of the Enterobacteriaceae (*Escherichia coli, Klebsiella pneumonia*), including some ESBL-producing strains, and *Pseudomonas aeruginosa*. It also has activity against *Streptococcus* spp. and *Staphylococcus* spp. Formulations are typically in 8 : 1 ratio of piperacillin : tazobactam available in injectable vials reconstituted with sterile water, 0.9% saline solution, or 5% dextrose in water, and further diluted to desired volume for intravenous fluid administration.

The pharmacokinetics have been studied in dogs. The combined analysis of seven different studies showed that it has a half-life of only 0.55 (± 0.11) hours and a volume of distribution of 0.276 (± 0.05) l/kg. The short half-life requires frequent administration (every 6 hours), or as a constant rate infusion (CRI). In immunocompetent animals it may be administered at a dose of 50 mg/kg every 6 hours IV (higher doses are needed in immunosuppressed animals), or as a CRI of 3.2 mg/kg/hour after a loading dose of 2.25 mg/kg. The breakpoint is listed in Table 33.1.

New β-lactamase inhibitor combinations: There are new β-lactamase inhibitor combinations, but there is no record of their use in veterinary medicine. Ceftazidime–avibactam (Avycaz) and ceftolozane–tazobactam (Zerbaxa) are approved for IV treatment of infections in people. They are third-generation cephalosporin/ β-lactamase inhibitor combinations (discussed in Section Cephalosporins) with a spectrum that includes many ESBL-producing bacteria and *Pseudomonas aeruginosa*. Ceftazidime–avibactam also has activity against some carbapenemase-producing *Klebsiella pneumoniae*. These drugs are used in people primarily for complicated urinary tract and intraabdomnial infections caused by bacteria resistant to other drugs.

Cephalosporins

Cephalosporins that are veterinary labeled, as well as drugs approved for humans (e.g., ceftazidime, cefotaxime, cefazolin), have commonly been used in veterinary medicine for many infections, including pyoderma, urinary tract infection, pneumonia, soft-tissue infection, osteomyelitis, and pre- and postsurgical use. They are often considered first-line treatments, often employed empirically for routine outpatient and in-hospital use. One of the advantages of the use of the generic formulations intended for humans is their low cost. For more resistant infections caused by *Pseudomonas aeruginosa* or the Enterobacteriaceae such as *E. coli*, extended-spectrum drugs of the third and fourth generation have been used.

General Pharmacology

The spectrum includes most bacteria susceptible to amoxicillin and ampicillin, but also includes some β-lactamase-producing bacteria, depending on the specific generation of cephalosporin. Many in this class have greater activity against gram-negative bacteria than amoxicillin or ampicillin. In general (exceptions are noted in Section Classification), the cephalosporins owe their usefulness to activity against *Staphylococcus* (β-lactamase–positive, but not methicillin-resistant strains), streptococci (but not enterococci), and gram-negative bacteria, except *Pseudomonas* (exceptions noted in Section Classification). Although cephalosporin antibiotics show activity against some anaerobic bacteria, they are ordinarily *not* considered a drug of choice for the gram-negative anaerobes. The cephamycins (a subclass of cephalosporins), however, have good anaerobic activity.

Cephalosporins contain a 7-aminocephalosporanic acid nucleus, which is composed of a β-lactam ring fused with a six-membered dihydrothiazine ring (see Figure 33.1). Additions of various groups (shown by the asterisk in Figure 33.1) form derivatives with differences in antimicrobial activity, stability against β-lactamases, protein binding, intestinal absorption, metabolism, and toxicity.

The cephalosporin antibiotics are extremely important in veterinary medicine. They were first produced by a fungus isolated from raw sewage from the sea in Sardinia. Although the antibiotic was first isolated from *Cephalosporium acremonium* in 1948, it was not available commercially until 1962. There are now over 30 cephalosporin antibiotics on the market (most on the human pharmaceutical market), but newer ones have been introduced to veterinary medicine. Although the cephalosporins are widely used in many animal species, the extralabel dosages of these drugs in food-producing animals is not allowed in the United States. Regulatory control of antibiotics in the USA is discussed in Chapter 52 and 55 of this book.

Classification

The cephalosporins are broadly classified into first-, second-, third-, and fourth-generation cephalosporins. There is also a new group active against methicillin-resistant staphylococci that has been called a *fifth* generation (e.g., ceftobiprole and ceftaroline) but there is no record of their use in veterinary medicine. This classification system is somewhat arbitrary, depending on when they were synthesized. This classification is largely based on activity against gram-negative bacteria and susceptibility to β-lactamase. Various other classifications of cephalosporins have been proposed (Williams et al., 2001). For this chapter, we retain the classification categories listed by the CLSI (CLSI, 2015) provided in Table 33.5.

First Generation

The first-generation drugs are effective against almost all gram-positive bacteria, except *Enterococcus*, and their activity includes β-lactamase-positive staphylococcus. They also have greater activity against members of the Enterobacteriaceae than penicillin G. Compared to others in this group, cefazolin has the greatest gram-negative activity (Petersen and Rosin, 1995), and it has been grouped with the second-generation drugs in some references based on this activity (Williams et al., 2001). Gram-negative bacteria may develop resistance by inhibiting penetration and by producing β-lactamase enzymes.

Second Generation

In general, these drugs have greater activity against many gram-negative bacteria that are resistant to the first-generation drugs (e.g., resistant *E. coli, Klebsiella, Proteus, Enterobacter*), but are no more active against the gram-positive bacteria. Improved activity against gram-negative bacteria compared to first-generation drugs is attributed to an increased resistance to β-lactamases. Cefoxitin and cefotetan belong to the cephamycin group and have been used clinically because of good activity against anaerobic bacteria (e.g., *Bacteroides fragilis,* and the *Bacteroides fragilis* group). Cefotetan is no longer available in the USA, but cefoxitin is still used in veterinary patients. Cefaclor (Ceclor®), cefprozil (Cefzil®), and cefuroxime axetil (Cefetin®) can be administered orally, but their use has not been reported for small animals.

Third Generation

This group of antibiotics has more activity against gram-negative bacteria than the earlier generations of cephalosporins. Only ceftazidime and cefoperazone have good activity against *Pseudomonas aeruginosa*, with ceftazidime having the greatest activity. For this reason, ceftazidime has been an important drug for some infections in small animals.

The third-generation drugs, in general, are less active against gram-positive cocci, but there is considerable variability in the activity against staphylococci and

Table 33.5 Classification of cephalosporins

First generation		Second Generation		Third generation	
Drug name	**Brand name**	**Drug name**	**Brand name**	**Drug name**	**Brand name**
cephalexin	generic, Keflex[a]	cefamandole	Mandol	cefoperazone	Cefobid
cephalothin	Keflin	cefmetazole	Zefazone	cefotaxime	Claforan
cefadroxil	Cefa-Tabs[a]	cefonicid	Monocid	ceftazidime	Fortaz

		cefaclor	Ceclor[a]	ceftiofur	Naxcel
				cefpodoxime proxetil	Vantin[a]
					Simplicef[a]
				Cefovecin	Convenia

[a] Oral drugs.

Fourth-generation drugs not listed include cefquinome (Cobactan) (veterinary drug) and cefepime (Maximime).

streptococci among this group. For example, cefotaxime has the highest activity against streptococci, but others have less activity. Some of the third-generation agents are more active against *Staphylococcus* spp. than cephalexin. There are only three that can be administered orally. Of these, two have been used in veterinary medicine, cefixime (Suprax®) (Lavy et al., 1995), and cefpodoxime proxetil (Simplicef veterinary formulation and Vantin human formulation). Cefixime is no longer available in the USA.

The human-labeled injectable third-generation drugs have been used in veterinary medicine when resistance has been shown to other drugs. An exception is ceftiofur (Naxcel®), which has been used extensively in cattle, pigs, and horses, and is also approved for use in dogs. The activity of the major metabolite, desfuroylceftiofur, is similar to cefotaxime, which is considered a typical third-generation cephalosporin. Cefovecin (Convenia), is an injectable formulation that has an extremely long half-life in dogs and cats compared to other cephalosporins. Specific agents are discussed in more detail in Section Clinical Features and Specific Drugs Used in Veterinary Medicine.

Fourth Generation

The fourth generation of cephalosporins include the human drug cefepime (Maxipime®), and the veterinary drug cefquinome (Cobactan). The use of cefepime has not been reported in veterinary medicine except for some experimental studies. Cefquinome is approved in other countries, but not the USA. These drugs are discussed in more detail in Section Clinical Features and Specific Drugs Used in Veterinary Medicine.

Mechanism of Action

Similar to other β-lactam antibiotics, the cephalosporins bind to PBPs and disrupt the cell wall. They are usually bactericidal and most often bind the PBP-2 and PBP-3.

Pharmacokinetics

The pharmacokinetic features of specific drugs are provided in Table 33.6.

Pharmacokinetics–Pharmacodynamics

Pharmacokinetic–pharmacodynamic (PK-PD) relationships for cephalosporins are the same as for other β-lactam antibiotics discussed in this chapter. Like other β-lactam antibiotics, cephalosporins are considered to be bactericidal in action; they kill bacteria if the drug concentrations are maintained above the MIC for a critical period during the dosing interval (Turnidge, 1998). Thus the important parameter is considered time above MIC (T > MIC). It is the duration of exposure, rather than the magnitude of the concentration above the MIC that determines efficacy of cephalosporins. Dosage regimens for the cephalosporins have been formulated to consider these PK-PD relationships (Craig, 1995, 2001; MacGowan, 2001; Turnidge, 1998). Among the β-lactams, penicillins are not as bactericidal as carbapenems, and cephalosporins are not as bactericidal as penicillins. Therefore, among the β-lactams, cephalosporins should be maintained above the MIC longer than others in this class. Although the optimum time above the MIC has not been determined for most cephalosporins used in companion animals, in humans and laboratory animals the optimum time above the MIC is regarded as approximately 50% of the dosing interval. However, for treating gram-negative infections, maximum bactericidal effect occurs at 60–70% of the dosing interval, and as the duration of the T > MIC increases, improved clinical outcomes are possible. In some experimental studies the T > MIC may be less than 50%. For example, when four cephalosporins were examined to determine the T > MIC necessary for optimum dosing, the T > MIC was 30–40% of the dosing interval for Enterobacteriaceae and *Streptococcus*, but less than 30% for *Staphylococcus*.

Because the half-lives of most cephalosporins in mammals are short, many regimens for cephalosporins use require an administration frequency of three to four times per day. Alternatively, some of the third-generation cephalosporins have long half-lives, and less frequent regimens have been used for some of these drugs (for example cefpodoxime, cefovecin, cefotaxime, and ceftiofur). However, the long half-life for ceftriaxone in people does not occur in animals because of differences in drug–protein binding (Popick et al., 1987).

The dosing regimen that produces the greatest T > MIC is the CRI, and superior efficacy has been reported from CRI regimens rather than intermittent dosing (Zeisler et al., 1992). Constant rate intravenous infusions have also been calculated for some third-generation cephalosporins for dogs (Moore et al., 2000).

Gram-positive organisms are more susceptible to the bactericidal effect of cephalosporins than are gram-negative bacteria. Additionally, since the MICs are lower for gram-positive bacteria, and antibacterial effects occur at concentrations below the MIC for *Staphylococcus* (postantibiotic effect, PAE), longer dose intervals may be possible for infections caused by gram-positive as compared to gram-negative bacteria. For example, cephalexin or cefadroxil have been used successfully to treat staphylococcal infections when administered twice daily (discussed further in Section Clinical Features and Specific Drugs Used in Veterinary Medicine). Some studies have reported efficacy for cephalexin treating staphylococcal pyoderma in dogs with administration of only once daily (although twice-daily

administration is recommended to obtain maximum response).

Susceptibility Testing

Breakpoints for susceptibility testing have been approved by CLSI for testing many of the cephalosporins used in veterinary medicine. These breakpoints are based on PK-PD analysis, MIC distributions, and clinical efficacy (Table 33.7).

Tissue Concentrations and Protein Binding

Cephalosporins are relatively polar antibiotics. They are minimally lipid soluble and have poor intracellular penetration. The volume of distribution is generally in the range of 0.2 to 0.3 l/kg and rarely exceeds 0.5 l/kg. However, they have good distribution into the extracellular fluid of most tissues, except prostate and the CNS. They do not reach effective intracellular concentrations. Their ability to penetrate the epithelial lining fluid of the respiratory tract varies among drugs and across species. Specific features of each drug will be discussed in more detail later in this chapter.

Pharmacokinetic–pharmacodynamic-based dosing regimens use plasma concentrations of the unbound drug as the surrogate marker for determining the optimum dose and interval. Only protein-unbound drug is microbiologically active. Protein binding varies across species and among the drugs. Some cephalosporins are highly protein bound, but for others it is low. There are differences between animals and people that affect their use. For example, ceftriaxone has high protein binding of 90–95% in people, which restricts clearance and causes a long half-life (Popick et al., 1987). But the same drug in dogs has protein binding of only 25% at low concentrations to 2% at high concentrations. Cefazolin has high protein binding in people (85%), but low protein binding in dogs (19%), which favors rapid distribution from plasma to interstitial fluid. The most highly protein-bound cephalosporin in animals is cefovecin, which is greater than 99% bound in dogs and cats, but much lower in some other animal species. This property, in addition to other factors, prolongs the plasma concentrations in dogs and cats.

The effect of protein binding on drug distribution was demonstrated for cephalexin and cefpodoxime, two orally administered cephalosporins used in dogs (Papich et al., 2007). Protein binding is higher for cefpodoxime in dogs (>80%), which prolongs the half-life compared to

Table 33.7 Susceptibility breakpoints for cephalosporins (as approved by CLSI 2013, 2015)

Test/report group	Body site	Antimicrobial agent	MIC interpretive criteria (μg/ml) S	I	R	Comments
Dogs	Skin, soft tissue	Cephalexin	≤2	4	≥8	Cephalexin breakpoints were determined from an examination of MIC distribution of isolates, efficacy data, and PK-PD analysis of cephalexin. The dosage regimen used for PK-PD analysis of cephalexin was 25 mg/kg administered every 12 hours orally.
Dogs	Skin, soft tissue, UTI, respiratory	Cefazolin	≤2	4	≥8	Cefazolin breakpoints were determined from an examination of MIC distribution of isolates and PK-PD analysis of cefazolin. The dosage regimen used for PK-PD analysis of cefazolin was 25 mg/kg administered every 6 hours IV in horses and dogs.
Dogs	Wounds, abscesses	Cefpodoxime	≤2	4	≥8	Approved for dogs at a dose of 5–10 mg/kg once daily orally.
Horses	Respiratory, genital tract	Cefazolin	≤2	4	≥8	Cefazolin breakpoints were determined from an examination of MIC distribution of isolates and PK-PD analysis of cefazolin. The dosage regimen used for PK/PD analysis of cefazolin was 25 mg/kg administered every 6 hours IV in horses.
Horses	Respiratory disease	Ceftiofur	≤0.25	–	–	The susceptible only category is used for populations of organisms (usually one species) for which regression analysis (disk vs. MIC) cannot be performed. This breakpoint will permit detection of strains with decreased susceptibility as compared to the original population.
Swine	Lung (SRD)	Ceftiofur	≤ 2	4	≥ 8	Approved for treating swine respiratory disease.
Cattle	Lung (BRD)	Ceftiofur	≤2	4	≥8	Approved for treating bovine respiratory disease.
Cattle	Bovine mastitis	Ceftiofur	≤ 2	4	≥ 8	Mastitis treatment only.

BRD, bovine respiratory disease; SRD, swine respiratory disease; PK, pharmacokinetic; PD, pharmacodynamic; R, resistant; I, intermediate; S, susceptible; UTI, urinary tract infection. Note that some laboratories have used cephalothin as a test for the first-generation cephalosporins such as cephalexin.

cephalexin. The free drug concentration for cefpodoxime in tissue fluid represented the unbound drug fraction in plasma, reflecting the effect of protein binding to restrict drug diffusion from capillaries into tissues. This phenomenon has also been observed in humans (Liu et al., 2002).

Oral Absorption

Many of the cephalosporins are absorbed orally. Cefadroxil and cephalexin of the first-generation group are well absorbed in small animals, but not in large animals. Oral absorption of the ester formulations (cefpodoxime proxetil) is enhanced. This feature will be discussed in more detail for individual drugs in Section Clinical Features and Specific Drugs Used in Veterinary Medicine. For cefadroxil, but not cephalexin, absorption was enhanced somewhat with food (Campbell and Rosin, 1998).

Oral absorption of cephalosporins is generally too low to be effective in horses and ruminants. However, cefadroxil is absorbed better in the foal than in adult horses (Wilson et al., 1985; Duffee et al., 1989). Oral absorption of cephalexin is low in horses (5%) (Davis et al., 2005) but at 30 mg/kg orally q 8 h, concentrations can be maintained above the MIC of highly susceptible bacteria.

Metabolism

Cephalosporins are minimally metabolized by the liver, but degree of metabolism can vary widely among the various drugs. Ceftiofur is transformed almost completely to the metabolite desfuroylceftiofur, which is responsible for its antibacterial efficacy. Most cephalosporins rely on renal elimination.

Elimination

The cephalosporins are eliminated rapidly after systemic administration. The route of elimination is primarily renal, and concentrations in the urine are usually high. This feature makes cephalosporins good choices for treatment of urinary tract infections.

In general, the cephalosporins have half-lives of 1 to 2 hours, but some (particularly the third-generation cephalosporins) may have longer half-lives, which may allow for infrequent dosing. For example, ceftiofur is metabolized to an active metabolite and has a half-life of approximately 3–6 hours in cattle, 4 hours in dogs, and 2.5 hours in horses.

Clinical Features and Specific Drugs Used in Veterinary Medicine

The drugs in the first-generation group have a spectrum of activity that includes staphylococci and streptococci. Resistance among gram-negative bacteria develops easily, primarily from synthesis of β-lactamase enzymes that can hydrolyze these drugs. Resistance has been demonstrated in clinical studies in which samples were collected from dogs and cats (Thungrat et al., 2015; Oluoch et al., 2001; Walker et al., 2000; Cooke et al., 2002). Some older studies may have underestimated resistance because older breakpoints were higher than current values (Table 33.7). Most of the enteric gram-negative isolates are resistant to first-generation cephalosporins because most wild-type bacteria of the Enterobacteriaceae have MIC values above the susceptible breakpoint for cephalexin. The second, third, and fourth generation have higher activity against the gram-negative pathogens. The situations in veterinary medicine in which extended-spectrum cephalosporins are most often used are for treatment of bacterial infections that are resistant to other drugs. The bacteria often identified in these resistance problems have been *Escherichia coli, Klebsiella pneumoniae, Enterobacter* species, *Proteus* species (especially indole positive), and *Pseudomonas aeruginosa*.

First-Generation Cephalosporins

Veterinarians are familiar with the cephalosporins commonly referred to as the *first-generation cephalosporins* represented by the oral drugs cephalexin (Keflex, Rilexine, and generic forms) and cefadroxil (Cefa-Tabs, Cefa-Drops), and the injectable drug cefazolin (generic). Cefadroxil and cephalexin have been the most extensively used of the oral first-generation cephalosporins in dogs. (Older drugs such as cephradine are no longer available.) Cefadroxil is more lipophilic than cephalexin and has the advantage of being better absorbed orally. The differences between cephalexin and cefadroxil were illustrated in the study by Campbell and Rosin (1998) in which they examined the oral absorption of each drug and the influence of food in dogs after 30 mg/kg every 12 hours. Being more lipophilic, cefadroxil was absorbed better when administered with food and attained higher concentrations in plasma. Cephalexin was less influenced by the presence of food. Every 12-hour dosing is appropriate to maintain concentrations above the MIC (Campbell and Rosin, 1998; Papich et al., 2007).

Cefadroxil: Cefadroxil is available as oral suspension (50 mg/ml) and oral tablets (although the availability of some formulations has diminished in recent years). In cats, cefadroxil pharmacokinetics are similar to that in dogs (Chatfield et al., 1984) and it has a half-life of 2.5 to 2.7 hours. Clinical trials in cats showed that cefadroxil was effective for dermal infections with cure rates of 88% at 10–20 mg/kg and 100% cure rate at 20 mg/kg twice daily. Cefadroxil also is used for urinary tract infections in cats at a dose of 20 mg/kg once daily.

In dogs, cefadroxil has been effective for treatment of urinary tract infections, skin infections, and respiratory infections (Chatfield et al., 1984; Angarano and MacDonald, 1989; Barsanti et al., 1985). The dose for which efficacy has been demonstrated for pyoderma has been 22 mg/kg every 12 hours orally for 21 to 30 days, but efficacy at a once-daily dose of 20 mg/kg once daily also has been reported (Scarampella et al., 2000). Cefadroxil at a dose of 22 mg/kg every 12 hours for 21 days was effective in an experimental model of canine cystitis (Barsanti et al., 1985) and has been approved for dogs for the treatment of urinary tract infections.

Cephalexin: Cephalexin is perhaps the most common oral cephalosporin administered to dogs. There is a chewable canine formulation (Rilexine) and approved formulations available in other countries. Human generic formulations also are administered to animals. Pharmacokinetics are listed in Table 33.6, which summarizes the results from several studies. Its oral absorption ranges from 57% to 73–79% (Lavy et al., 1997; Carli et al., 1999). Another study (Wackowiez et al., 1997), reported oral absorption of 91% in dogs. Most methicillin-susceptible *Staphylococcus* spp. and *Streptococcus* spp. are susceptible and cephalexin is appropriate for these infections in dogs and cats. One of the most common uses is staphylococcal pyoderma in dogs, for which there is established efficacy at a dose of 22–25 mg/kg q 12 h, oral. However, as noted above, most wild-type organisms of the Enterobacteriaceae (e.g., *E. coli, Klebsiella* spp.) are resistant. All *Pseudomonas aeruginosa* are resistant.

Oral absorption of cephalexin in cats is about 56%, with a half-life of 2.25 hours (Wackowiez et al., 1997). At usual recommended doses, this will maintain concentrations for pathogens in cats that cause dermal or urinary tract infections with 12-hour dosing. Cephalexin oral absorption in horses is only 5% (Davis et al., 2005), but can be administered at 30 mg/kg q 8 h orally to achieve effective plasma concentrations above 0.5 μg/ml.

Cefazolin: Cefazolin is the injectable cephalosporin administered often to companion animals. It is inexpensive, has a broad spectrum of activity, and is stable after reconstitution for 1 week if refrigerated (Bornstein et al., 1974). It has been administered IV, IM, and SC to dogs. There are several papers that have examined its activity and pharmacokinetics in animals (Petersen and Rosin, 1995; Rosin et al., 1989, 1993; Dickson et al., 1987; Marcellin-Little et al., 1996). Pharmacokinetics are shown in Table 33.6. It is more active against *E. coli* than cephalothin or cephalexin, and after standard doses of 20–22 mg/kg IV, concentrations can be maintained during surgical procedures. Cefazolin has low plasma protein binding (19% in dogs, which is much lower than in humans) and diffuses into tissue fluid to reach concentrations that parallel those in plasma (Rosin et al., 1989, 1993). Cefazolin also penetrated normal and osteomyletic bone in concentrations similar to plasma concentrations (Daly et al., 1982). Distribution was not impaired in osteomyletic bone. This advantage of good penetration has allowed it to be used for prevention and treatment of bone infections (Daly et al., 1982) and as a common antibiotic to use prophylactically prior to orthopedic surgery (Rosin et al., 1993). Richardson et al. (1992) showed that at a dose of 22 mg/kg IV every hour, cefazolin concentrations in bone were above the MIC_{90} for pathogens causing common postoperative infections. Concentrations in bone of dogs paralleled the plasma concentrations and the optimum dose for orthopedic surgery was determined by Marcellin-Little et al. (1996). To maintain cefazolin concentrations above 20 μg/ml (10× the MIC_{90} of susceptible organisms a dose of 22 mg/kg administered IV every 2 hours or 8 mg/kg administered IV every hour was determined. During surgery, disease, anesthesia, and blood loss may affect distribution and clearance of some drugs. However, when cefazolin was administered to dogs with hemorrhagic shock, the clearance was slower, but it was offset by an increased volume of distribution (Dickson et al., 1987). Consequently, the plasma concentrations were not different in dogs when compared before and after shock. Some cephalosporins affect blood clotting and platelet function in animals and may be risky to use prior to surgery. However, when cefazolin was compared to cephalothin and cefmetazole in dogs, the investigators showed that cephalothin decreased platelet aggregation, and cefmetazole prolonged bleeding time (Wilkens et al., 1994), but cefazolin caused no adverse effects on platelet aggregation, bleeding time, platelet count, platelet size, or bleeding times.

Cefazolin is used occasionally in horses as an injectable preoperatively or perioperatively. The current doses are derived from pharmacokinetics and susceptibility data (Table 33.6, 33.7). Cefazolin has a slower terminal half-life from IM than from IV administration. The IM injection is thought to have a longer half-life because of slower absorption from muscle (caused by the flip-flop effect). Subsequent doses of 10 to 20 mg/kg can be administered q 8 h IM or q 6 h IV.

Cephapirin: Cephapirin is not used very often for systemic use in animals, but there are dry cow and lactating cow preparations (Cefa-Dri®, Cefa-Lak®, respectively) of cephapirin for intramammary infusion. Cephapirin is used for treatment of mastitis caused by *Streptococcus* or *Staphylococcus*. Cephapirin benzathine is used for dry cow treatment 300 mg/10 ml, administered in each quarter at the time of drying. Cephapirin sodium 200 mg/10 ml is infused 200 mg to each affected quarter every 12 hours.

Second-Generation Cephalosporins

Of the second-generation cephalosporins, the one used most often in veterinary medicine is cefoxitin (Petersen and Rosin, 1993). Cefotetan was once used, but is no longer available commercially. The use has been valuable for treating organisms resistant to the first-generation cephalosporins or in cases in which there are anaerobic bacteria present. Anaerobic bacteria such as those of the *Bacteroides fragilis* group can become resistant by synthesizing a cephalosporinase enzyme, but cefoxitin and cefotetan, which are in the cephamycin group, are resistant to this enzyme. Therefore, this group has been valuable for some cases such as septic peritonitis that may have a mixed population of anaerobic bacteria and gram-negative bacilli.

There are no reports of clinical use of oral second-generation cephalosporins in small animals, but doses have been extrapolated from human studies. Cefaclor was shown to have 75% oral bioavailability in dogs and there are anecdotal accounts of its use (Waterman and Scharfenberger, 1978). Interstitial drug levels were lower than serum, but urine concentrations were high for 4 hours after dosing.

Third-Generation Cephalosporins

The third-generation cephalosporins are the most active of the cephalosporins against gram-negative bacteria,

Table 33.8 Dose, formulations and indications for ceftiofur in animals

Species	Formulation	Dose
Cattle	Ceftiofur crystalline free acid (Excede)	6.6 mg/kg, with a single SQ injection in the middle third of the posterior aspect of the ear.
Horses and Foals	Ceftiofur crystalline free acid (Excede)	6.6 mg/kg IM in neck muscle (15 ml per 1,000 pounds). Administer a second dose in 4 days. Do not administer more than 20 ml in one site.
Pigs	Ceftiofur crystalline free acid (Excede)	5.0 mg/kg IM injection in the postauricular region of the neck.
Cattle	Ceftiofur hydrochloride (Excenel)	1.1–2.2 mg/kg q 24 h for 3 days IM or SQ. Intrauterine (retained fetal membranes): 1 g ceftiofur diluted in 20 ml sterile water infused in uterus once at 14–20 days after calving. Treatment of postpartum metritis: 2.2 mg/kg once daily for 5 days SQ or IM.
Pigs	Ceftiofur hydrochloride (Excenel)	3–5 mg/kg q 24 h for 3 days IM.
Cattle	Ceftiofur sodium (Naxcel)	Bovine respiratory disease (BRD): 1.1–2.2 mg/kg (0.5–1.0 mg/pound) q 24 h for 3 days IM. Additional doses may be given on days 4 and 5 if necessary. In cattle, these doses also may be administered SQ, which is bioequivalent.
Horses	Ceftiofur sodium (Naxcel)	2.2–4.4 mg/kg q 24 h IM or 2.2 mg/kg q 12 h IM for as long as 10 days. Treatment of some gram-negative infections may require doses at the higher range and up to 11 mg/kg/day IM has been given to horses. Foals: 5 mg/kg q 12 h IV, or CRI of 1 mg/kg/hour IV.
Pigs	Ceftiofur sodium (Naxcel)	Respiratory infections: 3–5 mg/kg (1.36–2.27 mg/pound) q 24 h for 3 days IM.
Sheep, goats	Ceftiofur sodium (Naxcel)	1.1–2.2 mg/kg (0.5–1.0 mg/pound) q 24 h for 3 days IM, SQ. Additional doses may be given on days 4 and 5 if necessary.
Dogs	Ceftiofur sodium (Naxcel)	Urinary tract infection: 2.2 to 4.4 mg/kg q 24 h SQ. Dose not established for cats but has been extrapolated from canine dose.

especially enteric organisms that are resistant to other cephalosporins. The injectable drugs are administered IV, SC, or IM. The SC route is often used for convenience (Moore et al., 2000; Guerrini et al., 1986). Veterinarians have observed that the IM or SC administration of some of these drugs can be irritating and painful. Cefotaxime (Claforan, and generic) is one of the typical members of this group to which others are compared. It has activity against most enteric gram-negative bacteria and some streptococci. Except for a few pharmacokinetic studies (Guerrini et al., 1986; McElroy et al., 1986), there are no published studies in which cefotaxime has been evaluated in veterinary patients. However, the pharmacokinetics between dogs and humans are similar enough that doses, as well as clinical uses, have been extrapolated from human medicine. Generally, cefotaxime is administered IV, IM, or SC to dogs and cats at a dose of 30 mg/kg every 8 hours. When administered SC to dogs, and IM to cats, the absorption was high (McElroy et al., 1986; Guerrini et al., 1986).

Ceftiofur: Ceftiofur (Naxcel, Excenel, Excede) has been approved for veterinary use for many years. It is unique because it is not used in human medicine. It is available in three forms: (i) ceftiofur sodium – Naxcel, (ii) ceftiofur hydrochloride suspension (Excenel), and (iii) ceftiofur crystalline free acid (Excede). After injection it is converted to an active metabolite, desfuroylceftiofur. The differences in activity between ceftiofur and its metabolite were reported by Salmon et al. (1996). Ceftofur has greater activity than the desfuroyl metabolite against *Staphylococcus* spp. (four to eight times difference) and slightly greater activity against *Streptococcus* spp. Both the parent drug and metabolite are highly active against gram-negative bacteria that cause bovine and porcine respiratory disease, but less so against gram-negative bacteria of the Enterobacteriaceae (MIC 0.5–1 μg/ml). The CLSI (CLSI, 2015) breakpoint for ceftiofur use in cattle and swine is ≤2.0 μg/ml (Table 33.7), but lower for the use in horses. Doses are listed in Table 33.8.

For dogs ceftiofur sodium is approved only for treating urinary tract infections caused by gram-negative bacilli of the Enterobacteriaceae at a dose of 2.2 mg/kg SC once a day. Bacteria with higher MIC values may require larger doses or more frequent administration (Brown et al., 1995). The use of ceftiofur for treating systemic infections in small animals has not been reported; but, on the basis of the pharmacokinetic profile of plasma concentrations (Brown et al., 1995), it appears that the frequency of administration should be greater than once a day to maintain the drug concentrations above the MIC for a sufficient duration. In dogs, anemia and thrombocytopenia are possible if ceftiofur is administered at doses of three times and five times the registered dose of 2.2 mg/kg.

Ceftiofur is the most frequently used cephalosporin in horses. Ceftiofur was approved for use in horses for treatment of respiratory tract infections caused by *Streptococcus equi* subsp. *zooepidemicus* at a dose of 2.2 to 4.4 mg/kg q 24 h IM. Higher doses or more frequent intervals have been recommended for treating gram-negative organisms (e.g., *Klebsiella, Enterobacter, Salmonella*). Because these organisms are inherently more resistant, higher plasma concentrations are needed for efficacy. Studies in foals indicated that a dose of 2.2 to 6.6 mg/kg could be given to foals IM or IV q 12 h for treatment of neonatal sepsis. Based on pharmacokinetic studies (Jaglan et al., 1994) a dose of 4.4 mg/kg injected q 12 h will produce plasma concentrations above the MIC to meet the criteria for effective therapy. Toxicity studies have shown that horses tolerate ceftiofur doses up to 11 mg/kg/day IM, with pain at the injection site and decreased feed consumption as the most common adverse effects at the highest dose.

An important use of ceftiofur is for respiratory and other infections in cattle and pigs. An advantage of ceftiofur is that concentrations quickly fall below the allowed tolerance and withdrawal times for slaughter and milk are short compared to other antibiotics. Use of this drug in food animals is discussed further in Chapter 52 of this book. It has been used for treating bovine respiratory disease (BRD) in cattle and swine respiratory disease (SRD) in pigs. It has activity against bovine and swine respiratory pathogens such as *Actinobacillus pleuropneumoniae, Mannheimia haemolytica, Histophilus somni, Salmonella choleraesuis, Haemophilus*, and *Streptococcus*. This formulation also is approved for treating foot rot in cattle (interdigital necrobacillosis) caused by *Fusobacterium necrophorum, Porphyromonas levii,* and *Bacteriodes melaninogenicus*. It is approved for treatment of acute metritis in dairy cattle via a two-dose regimen. The crystalline-free acid (Excede) is a slow-releasing drug that is injected at the base of the ear in cattle and in the neck of pigs. Ceftiofur hydrochloride and ceftiofur crystalline-free acid have also been administered intramammary to dairy cattle (Spectramast).

Ceftazidime: Compared to other cephalosporins, ceftazidime is the most active against *Pseudomonas aeruginosa*, against which all the other cephalosporins, except cefoperazone, have little or no activity. Ceftazidime has been studied in dogs (Moore et al., 2000; Matsui et al., 1984; Acred, 1983) and it has a short half-life (less than 1 hour) and volume of distribution similar to that in humans. Dosages have ranged from 20–30 mg/kg every 12 hours for Enterobacteriaceae, to 30 mg/kg administered every 4 hours for *Pseudomonas aeruginosa* (Moore et al., 2000).

In vitro activity of ceftazidime is good against most gram-negative bacilli (Martin Barrasa et al., 2000). Isolates of *Pseudomonas aeruginosa* from otitis media showed that 97% were susceptible to ceftazidime (Colombini et al., 2000). In a study that isolated *Pseudomonas aeruginosa* from the skin and ears of dogs, a similar pattern of susceptibility was reported (Petersen et al., 2002). In a study that examined 183 isolates of *Pseudomonas aeruginosa* from various sites in dogs (1993–2000), Seol et al., 2002), 77% were susceptible to ceftazidime.

Because of the good activity against Enterobacteriaceae and *Pseudomonas aeruginosa*, ceftazidime has been used in exotic and zoo animals. In a killer whale, the half-life was greater than 6 hours after IM administration and therapeutic concentrations were maintained after doses of 20 mg/kg every 24 hours, IM (unpublished observations by the author, MGP). In reptiles, cephalosporins are excreted slowly. Ceftazidime pharmacokinetics in sea turtles determined that a half-life of 20 hours allowed for dosing of 20 mg/kg as infrequently as every 72 hours (Stamper et al., 1999). In Eastern box turtles the half-life was 42 hours, which allows for a dose of 20 mg/kg IM every 5 days to maintain concentrations above a therapeutic range (author's data; not yet published).

Cefovecin: In December 2006, cefovecin (Convenia) was introduced to small animal medicine in Europe. The same drug and formulation were available in Canada in October 2007 and in the US in 2008. Pharmacokinetic studies have shown the unique differences between cefovecin and other cephalosporins in dogs and cats (Stegemann et al., 2006b, 2006c). Efficacy studies and clinical field trials have shown its efficacy (Stegemann et al., 2007a, 2007b; Passmore et al., 2007). In the clinical studies, cefovecin was compared to another active antimicrobial (cefadroxil, cephalexin, or amoxicillin–clavulanate) and was found noninferior to these other drugs.

In dogs and cats, cefovecin is approved for treatment of skin and soft-tissue infections. In some countries it is also registered for urinary tract infections. The approved label dose in the US allows for a repeat injection at 7 days at a dose of 8 mg/kg SC. However, concentrations are maintained against some bacteria for 14 days, and the approved labeling in Canada and Europe lists a 14-day dose interval. The studies published show efficacy with a 14-day interval for administration. The injection may be repeated if longer than 14 days is needed for a cure (e.g., canine pyoderma).

The long duration of cefovecin is attributed to the long half-life in dogs and cats. Cefovecin is >99% protein bound in cats and >98% in dogs. With such a small fraction unbound (fu) there is little drug available for excretion and some tubular reabsorption may also occur. Subsequently, the terminal half-life is approximately 7 days in cats and 5 days in dogs. Effective concentrations can be maintained in the tissue fluid for a 14-day interval or longer (Stegemann et al., 2006b, 2006c). Cefovecin is classified as a third-generation cephalosporin and has a low MIC values for many bacteria. Against pathogens from Europe and the US (Stegemann et al., 2006a), cefovecin MIC_{90} values were 0.25 μg/ml for *Staphylococcus pseudintermedius* compared to 2 μg/ml for cephalexin and cefadroxil. It has greater activity against gram-negative bacteria than first-generation cephalosporins, as was demonstrated by the MIC_{90} values of 1 μg/ml compared to 16 μg/ml for cephalexin and cefadroxil. Many other MIC comparisons are provided in the tables in the paper by Stegemann et al. (2006a). But compared to other third-generation cephalosporins such as cefotaxime, it is not as active against gram-negative bacteria of the Enterobacteriaceae.

Oral Third-Generation Cephalosporins

Because the drugs mentioned above are all injectable, there has been a need for an oral extended-spectrum cephalosporin. Cefixime (Suprax) was once used in small animals, but is no longer available (Lavy et al., 1995; Bialer et al., 1987).

Cefpodoxime proxetil: Cefpodoxime proxetil is the oral third-generation cephalosporin used most often in veterinary medicine. It is a prodrug ester (Borin, 1991) that is designed to remain stable in the stomach, but the prodrug is converted to the active cefpodoxime by intestinal brush border enzymes. As a lipophilic ester, it is anticipated that oral absorption will be enhanced if the drug is administered with food, which has been confirmed in people, but not specifically reported for dogs. Cefpodoxime has similar gram-negative in vitro activity as cefixime, but greater activity against *Staphylococcus*.

In dogs pharmacokinetics have been studied to show good oral absorption and a long half-life (4.7 and 5.6 hours) compared to other cephalosporins that allow for once-daily administration at 5–10 mg/kg (Brown et al., 2007; Klesel et al., 1992; Papich et al., 2007). Cherni and colleagues (2006) reported that cefpodoxime proxetil administered once a day (5 mg/kg) to dogs with pyoderma was as effective as twice-daily (26 mg/kg) administration of cephalexin (Cherni et al., 2006). In horses, cefpodoxime proxetil oral absorption was good enough that a dose of 10 mg/kg q 6–12 h produced plasma concentrations that would potentially treat infections in horses (Carrillo et al., 2005), but clinical use in horses has not been reported.

Fourth-Generation Cephalosporins

The only fourth-generation cephalosporin available in the US at this time is cefepime (Maxipime), which is approved for people and occasionally used in animals. It is unique because of its broad spectrum of activity that includes gram-positive cocci, enteric gram-negative bacilli, and *Pseudomonas aeruginosa*. It has the advantage of activity against some extended-spectrum β-lactamase (ESBL)-producing strains of *Klebsiella* and *E. coli* that have become resistant to other β-lactam drugs and fluoroquinolones. Except for investigations in dogs, adult horses, and foals, the use of cefepime has been limited in veterinary medicine (Gardner and Papich, 2001). In the study in dogs, there was a short half-life of 1 hour, and to maintain drug concentrations above an MIC value of 8 μg/ml for 67% of the dosing interval, a dose of 40 mg/kg IV every 6 hours would be necessary. However, this dose would maintain the concentration above an MIC of 2 μg/ml for 100% of the dosing interval and bacteria with lower MIC values (MIC ≤2 μg/ml) could be treated with longer dose intervals. In foals and mares this drug possibly could be used for infections resistant to other drugs. A cefepime dose for foals of 11 mg/kg IV q 8 h (Gardner and Papich, 2001) and for adults of 2.2 mg/kg IV q 8 h (Gardner and Papich, 2001; Guglick et al., 1998) is recommended. When cefepime was administered to horses orally, signs of colic were observed (Guglick et al., 1998).

Cefquinome (Cobactan) has been licensed for use in cattle and horses in Europe since 1994. It is not approved for use in the USA. It is approved for treatment of infections in horses and cattle caused by *Streptococcus equi subsp. zooepidemicus*, septicemia caused by *Escherichia coli*, and respiratory diseases caused by *Pasteurella multocida* and *Mannheimia haemolytica*, digital dermatitis, infectious bulbar necrosis and acute interdigital necrobacillosis (foul in the foot). It is also approved as an intramammary product for treatment of mastitis.

Adverse Reactions

Cephalosporins have a high therapeutic index and have been administered to small animals safely. Some of the adverse reactions are listed in the following sections.

Hypersensitivity Reactions

Hypersensitivity allergic reactions (type I, II, or III) have been observed in small animals after administration, but they are infrequently reported. There appears to be some cross-sensitivity with penicillins, but the incidence has not been reported. One should not assume that, if animals are sensitive to penicillin drugs, they will have adverse effects from cephalosporins. Sensitivity to penicillins may increase the risk of sensitivity to cephalosporins by a factor of 4 (Kelkar and Li, 2001), but many patients who are sensitive to penicillins can receive cephalosporins safely. Cephalexin has a side chain identical to that of amoxicillin, so animals with sensitivity to ampicillin should be administered cephalexin cautiously. Likewise, cefadroxil has the same identical side chain as amoxicillin.

Gastrointestinal

Some dogs vomit after receiving oral cephalosporins (e.g., cefadroxil, cephalexin), particularly at high doses. Dogs also may vomit after rapid injections of intravenous cephalosporins (Petersen and Rosin, 1993). In clinical studies with oral cephalosporins, vomiting and diarrhea are the most common adverse reaction (Frank and Kunkle, 1993). Cephalexin and cefadroxil were the third and fifth most common oral drugs to cause adverse events in dogs according to one survey (Kunkle et al., 1995). In this survey, the most common adverse effects associated with oral cephalosporins were gastrointestinal (vomiting, diarrhea, and loss of appetite). It is believed to be caused by irritation to the stomach mucosa, but the exact mechanism has not been investigated.

Blood Disorders

Cephalosporin-induced hemolysis has been reported in people (Ehmann, 1992). Such a disorder has not been reported from use of cephalosporins in small animals. A positive Coombs test reaction can occur with patients receiving cephalosporins, but it is not associated with hemolytic anemia. High doses of ceftiofur in dogs can cause anemia and thrombocytopenia.

Bleeding Disorders

Bleeding disorders have been reported with some cephalosporins in humans because they may produce a prolongation of the prothrombin bleeding time. Even though this effect can be demonstrated in experimental dogs, it has not been reported to be a clinical problem in veterinary medicine, probably because it is associated only with a few of the cephalosporins that are rarely used in animals. Cephalothin was shown to prolong mucosal bleeding times and adenosine diphosphate (ADP)-induced platelet aggregation in dogs, but did not affect platelet numbers or platelet aggregation from collagen (Schermerhorn et al., 1994). This is a moot point for cephalothin because it is no longer used clinically in dogs. Cefazolin is often administered to dogs, cats, and horses. When it was compared to cephalothin and cefmetazole in dogs, the investigators showed that cephalothin decreased platelet aggregation, and cefmetazole prolonged bleeding time (Wilkens et al., 1994). However, cefazolin caused no adverse effects on platelet aggregation, bleeding time, platelet count, platelet size, or bleeding times.

In people, only the cephalosporins with NMTT (*N*-methylthiotetrazole) side chains are prone to producing bleeding problems. *(The NMTT drugs include cefoperazone, cefotetan, and cefamandole.)* Bleeding problems appear to be related to vitamin K antagonism and/or platelet dysfunction.

Glycosuria

Cephalosporins may cause a false-positive glucose test on a urine sample test, but this occurs only if the test employs the copper-reduction test. Others such as the glucose enzymatic tests are not affected. This is of little clinical significance.

Special Species Considerations

In zoo hoofstock, ceftiofur and other cephalosporins are important injectable drugs. Pharmacokinetics are similar as in other large animals, and doses for the cephalosporins are similar among the large zoo species. Drugs such as ceftiofur crystalline free acid are important in these animals because they can be treated without the need for frequent injections.

In reptiles, cephalosporins are excreted slowly. Ceftazidime pharmacokinetics in sea turtles determined that a half-life of 20 hours allowed for dosing of 20 mg/kg as infrequently as every 72 hours (Stamper et al., 1999). Regimens for cephalosporins in other reptiles have been published that also allow for long dosing intervals (Jacobson, 1999).

In birds, rapid elimination and poor oral absorption are a problem. This requires high doses and frequent administration for cephalosporins (Flammer, 1998). Doses for cephalexin and cefotaxime in birds has been listed as high as 100 mg/kg, q 8 h.

Carbapenems (Penems)

Carbapenems (also called *penems*) include imipenem, doripenem, ertapenem, and meropenem. They have the broadest antibacterial action in comparison to other β-lactams, even surpassing third-generation cephalosporins. The carbapenems have become valuable antibiotics because of a broad spectrum that includes many bacteria resistant to other drugs (Edwards and Betts, 2000). Carbapenems are not active against methicillin-resistant staphylococci or resistant strains of *Enterococcus faecium*. The high activity of the carbapenem group of β-lactams is attributed to its stability against most of the β-lactamases (including ESBL) and ability to penetrate porin channels that usually exclude other drugs (Livermore, 2001). Resistance to carbapenems has been extremely rare in veterinary medicine, but as discussed earlier carbapenemase-producing bacteria have been identified in animals (Abraham et al., 2014).

The carbapenems have been used primarily for serious, resistant infections that would otherwise require multiple drugs, including aminoglycosides. They are more bactericidal than other β-lactam antibiotics against gram-negative bacteria because they affect PBP-1 and PBP-2 and produce postantibiotic effects (PAE) that are not seen with other β-lactams. The rapid bactericidal activity is less likely to induce release of endotoxin in patients from gram-negative sepsis during treatment. The bactericidal activity can be maintained with a shorter time above the MIC than other β-lactam antibiotics (Turnidge, 1998). In veterinary medicine, their use has been limited to serious infections caused by bacteria resistant to other antibiotics. Imipenem and meropenem are the most commonly used of this group. The breakpoints for susceptibility testing are not established for animals. For humans the susceptible breakpoint is ≤1 μg/ml for Enterobacteriaceae (≤0.5 μg/ml for ertapenem) and ≤2 μg/ml for *Pseudomonas aeruginosa.*

Imipenem (Primaxin®)

Imipenem has been used occasionally for treating serious infections in veterinary medicine. Imipenem is ordinarily metabolized extensively by the renal tubules (a brush border enzyme) to a potentially toxic compound. The drug cilastatin inhibits the renal enzymes and imipenem is combined with cilastatin in the product Primaxin® to avoid renal toxicity and to achieve high urine concentrations of active drug.

Some disadvantages of imipenem are the inconvenience of administration, short shelf-life after reconstitution, and high cost. It must be diluted in fluids prior to administration. A common dose for small animals is 10 mg/kg q 8 h or 5 mg/kg q 6 h. This dose must be given by constant rate infusion over 30–60 minutes, but it has been administered subcutaneously. One of the adverse effects caused from imipenem therapy is seizures. Another problem is the risk of renal injury, which should be minimized by the addition of cilastatin (Barker et al., 2003).

Meropenem (Merrem®)

Meropenem is a newer-generation carbapenem. It has antibacterial activity approximately equal to, or greater than, imipenem. Its advantage over imipenem is that it is more soluble and can be administered in less fluid volume and more rapidly. For example, small volumes can be administered subcutaneously with almost complete absorption. There also is a lower incidence of adverse effects to the central nervous system, such as seizures (Edwards and Betts, 2000). Based on pharmacokinetic experiments (Bidgood and Papich, 2002), the recommended dose in dogs for Enterobacteriaceae and other susceptible organisms is 8.5 mg/kg SC every 12 hours, or 24 mg/kg IV every 12 hours. For infections caused by *Pseudomonas aeruginosa*, or other similar organisms that may have MIC values as high as 1.0 μg/ml, the dose is 12 mg/kg q 8 h, SC, or 25 mg/kg q 8 h, IV. For susceptible organisms in the urinary tract, 8 mg/kg, SC, every 12 hours can be used. In the experience of the author, these doses have been well-tolerated except for slight hair loss over some of the SC dosing sites. The dose for cats, based on pharmacokinetic studies, is 10 mg/kg twice daily, SC, IM, or IV.

Ertapenem (Invanz)

Ertapenem is one of the newest of the carbapenems. Ertapenem has good activity against most gram-negative organisms, except *Pseudomonas aeruginosa.* It has a longer half-life in people, allowing for once-daily administration. However, in dogs the protein binding was only 46% and the half-life is not prolonged as it is in people. The half-life after a SC injection of 20 mg/kg was 1.3 hours with high systemic clearance. A dose of 30 mg/kg every 12 hours SC in dogs will maintain concentrations in the therapeutic range for dogs. The dose should be increased to every 8 hours in immunocompromised animals.

Tetracycline Antibiotics

Mark G. Papich and Jim E. Riviere

General Pharmacology of Tetracyclines

The tetracycline antibiotics were initially discovered in 1944, with the first one being chlortetracycline. These were isolated from the *Streptomyces* species (*S. rimosus* and *S. aureofaciens*), and later expanded to include the various semisynthetic products that include tetracycline, doxycycline, and minocycline. Oxytetracycline was discovered in 1948, tetracycline in 1953, doxycycline in 1967, and minocycline in 1972. The newest development is the glycylcyclines, which are derivatives of minocycline. Tigecycline is the only available representative of this group, which possesses better antimicrobial activity than older drugs (Agwuh and MacGowan, 2006). Tigecycline use in veterinary medicine has not been reported.

The tetracyclines are a group of four-ringed amphoteric compounds (Figure 34.1) that differ by specific chemical substitutions at different points on the rings. As a group, the tetracyclines are acidic, hygroscopic compounds in aqueous solutions and easily form salts with acids and bases, with which they are commonly formulated. The most common salt form is the hydrochloride formulation, as is the case with oxytetracycline. However, some tetracyclines, especially oxytetracycline, are formulated with vehicles (excipients) to prolong absorption from the injection site. Some of the chemical and physical properties of the tetracyclines used in veterinary medicine today are listed in Table 34.1.

Tetracyclines have activity against both gram-positive and gram-negative bacteria, but resistance occurs frequently. They also have activity against atypical pathogens such as *Mycoplasma*, blood-borne pathogens (hemoplasma), and organisms such as *Rickettsia* transmitted by ticks and other parasites. Clinically accepted indications include abscesses, enteritis, *Leptospirosis*, pneumonia, bovine and swine respiratory disease, pododermatitis, treatment of tick-borne pathogens, skin and soft tissue infections, canine heartworm disease, and uterine infections.

Many formulations have been administered in medicated water and for feed for production purposes (growth promotion). The US Food and Drug Administration (FDA) announced that as of 2017 the production uses of these antibiotics will be voluntarily withdrawn from livestock use. The tetracyclines comprise the largest group of antibiotics affected by this FDA order. The FDA believes that production use indications such as “increased rate of weight gain” or “improved feed efficiency” are no longer appropriate for the approved conditions of use for medically important antimicrobial drugs. These regulatory changes are provided in the Guidance for Industry (GFI) documents #209 and #213, which may be obtained from the FDA. These medications ordinarily added to feed and water of livestock will not be considered in this chapter because of their future status, and the levels administered are considered subtherapeutic. In addition, the pharmacokinetics of these formulations in the target species is incomplete.

Mechanism of Action

Tetracyclines possess antimicrobial activity by binding to the 30S ribosomal subunit of susceptible organisms. After binding to the ribosome, the tetracyclines interfere with the binding of aminoacyl-tRNA to the messenger RNA molecule/ribosome complex, thereby interfering with bacterial protein synthesis in growing or multiplying organisms (Gale and Folkes, 1953; Suzuka et al., 1966). Tetracyclines require an energy-dependent process to enter bacteria. One of the reasons for their selectivity against microorganisms is that mammalian cells lack this transport mechanism. Tetracyclines also have less affinity for mammalian ribosomes than bacterial ribosomes. Because the binding to the ribosome target is a reversible process, the drug concentrations must be maintained throughout the dose interval and these drugs are generally considered bacteriostatic. Details are described in Section Pharmacokinetic–Pharmacodynamic Properties.
